(54) VENTILATION/LAVAGE LIQUIDE DES POUMONS  
(54) LIQUID LAVAGE/VENTILATION OF THE PULMONARY  
SYSTEM

(57) The invention provides for the pulmonary administration of biologically active agents via liquid lavage/ventilation. A liquid medium comprising at least one biologically active agent and a liquid carrier is passed through at least a portion of the patient's pulmonary air passages. The liquid medium may be a breathable liquid, such as a perfluorocarbon liquid or physiological saline solution. Suitable perfluorocarbon liquids having the requisite physical and thermal properties are characterized by an average molecular weight in the range of from about 350 to about 560. Representative perfluorocarbon liquids are FC-84, FC-72, RM-82, FC-75, RM-101, and perfluorodecalin.

Industrie Canada Industry Canada

**LIQUID LAVAGE/VENTILATION OF THE  
PULMONARY SYSTEM**

This invention was made with government support under Small Business Innovation Research Program Grant No. 5 1 R43 CA48611-01 awarded by the Public Health Service, Department of Health and Human Services. The government has certain rights in the invention.

**Technical Field**

The invention relates to methods and means for 10 introducing liquids into the pulmonary system of patients for the treatment of pulmonary and/or systemic disease, conditions and/or abnormalities such as, for example, to effect hyperthermic treatment and augmented radiotherapy and chemotherapy of lung cancer. This invention also 15 relates to the employment of liquid as a means of delivering, through the pulmonary air passages of a patient, biologically active agents.

**Background of the Invention**

In the United States there has been a steady rise 20 in the age-adjusted national death rate from pulmonary related diseases. The overwhelmingly predominant contributor to this trend is lung cancer. Currently about 8% of all deaths in the industrialized world are attributed to lung cancer. In the United States, an estimated 155,000 25 new cases of lung cancer are currently diagnosed each year, and about 142,000 will die of the disease, about 1 death every 4 minutes! Only about 10% of the patients currently diagnosed with lung cancer will survive beyond 5 years.

Lung cancer, or bronchial carcinoma, refers strictly to tumors arising from the major airways (bronchi) and pulmonary parenchyma (bronchioles, alveoli, and supporting tissue), as opposed to those metastasizing from other sites. The four major forms of lung cancer, squamous cell carcinoma (SCC), adenocarcinoma (AC), large cell anaplastic carcinoma (LCAC), and small cell anaplastic carcinoma (SCAC), account for 98% of pulmonary malignancies. Although lung cancer can occur anywhere in the lungs, about three-quarters of primary lung cancers occur in and/or on the bronchial walls within the first three bronchial generations, i.e., near or proximal to the hilus, the region where the airways and major vessels enter and leave each lung. A smaller percentage occur in more distal areas of the parenchyma. Many tumors occur near the carina, at the junction of the right and left bronchi with the trachea, presumably due to increased deposition of inhaled carcinogens. Squamous cell carcinoma tumors, the most common histological type, making up 30-40% of lung tumors, arise inside the surface layer of the bronchial wall and then invade the wall and adjacent structures. Squamous cell carcinomas tend to be relatively localized with less tendency than the other lung cancer tumors to metastasize. Adenocarcinoma tumors, also comprising 30-40% of lung cancers, occur in the mid- to outer third of the lung in about three-quarters of the cases. Adenocarcinomas tend to metastasize widely and frequently to other lung sites, the liver, bone, kidney, and brain. Small cell cancer, accounting for about 20% of all lung cancer, is the most aggressively metastatic and rapidly growing, and can begin near the hilus or in the lung periphery. Large cell tumors account for only a few percent of lung cancer and can occur anywhere in the lung. "Local failure," where primary tumors spread to mediastinal lymph nodes, pleura, adrenal glands, bone, and brain, is common with adenocarcinoma,

small cell anaplastic carcinoma, and large cell anaplastic carcinoma, and less so in squamous cell carcinoma.

5       The current "curative" treatment for lung cancer is surgery, but the option for such a cure is given to very few. Only about 20% of lung cancer is resectable, and out of this number less than half will survive five years. Radiation therapy (RT) is the standard treatment for inoperable non-small cell cancer, and chemotherapy (alone or with radiation therapy) is the treatment of choice for 10 small cell and other lung cancer with wide metastasis. Patients with clinically localized but technically unresectable tumors represent a major problem for the radiotherapist, accounting for an estimated 40% of all lung cancer cases.

15       Adjunctive hyperthermia, the use of deep heating modalities to treat tumors, is being used increasingly to augment the therapeutic efficacy of radiotherapy and chemotherapy in cancer treatment. It has been estimated that eventually "hyperthermia will be indispensable for 20 20 to 25% of all cancer patients" [1; see the appended listing of literature citations]. Hyperthermia clinical research is increasingly showing the importance of using specialized heating equipment to treat specific anatomical locations and sites rather than devices with more general-purpose 25 heating capabilities. Unfortunately, current hyperthermia devices are ill-suited to providing deep, localized heating of lung cancer. Because of this limitation, very few applications of localized lung hyperthermia have been recorded in the literature [2].

30       Kapp [8] has shown that, in terms of absolute numbers of patients (15,000 in 1987), more lung cancer patients would benefit from effective local hyperthermia than in any other cancer category, with the possible exception of prostate carcinoma. Because of the present 35 difficulty of heating tumors locally in a controlled fashion in the center of the thorax, the techniques most

commonly attempted for lung cancer hyperthermia to date have been whole-body hyperthermia (WBH), and radio-frequency (RF) heating of locoregional lung areas [2,9]. While whole-body hyperthermia has produced some encouraging results in combination with chemotherapy, the technique is unsatisfactory since it produces significant systemic toxicity and mortality, and because the thermal dose is limited due to long induction times (warmup) and the need to maintain core temperatures below 42°C. The electromagnetic (EM) approaches to lung heating have also been disappointing, due to the unpredictability of the heating patterns produced, the difficulty of measuring intratumoral temperatures in electromagnetic fields, the propensity of radio-frequency heating to preferentially heat superficial fat, and because of the physical inability of electromagnetic modalities to produce small focal volumes. The modern microwave body-surrounding array systems also suffer from difficulties associated with localization and predictability of heating, thermometry artifacts, and heat spikes at fat muscle interfaces.

Because of its characteristically small wavelengths, therapeutic ultrasound has the best capability for providing local heating in the body of all the conventionally used hyperthermia modalities. Focused and unfocused ultrasound beams are routinely used clinically to successfully provide localized hyperthermia to many tumors residing in soft tissues and organs. However, the presence of air in the lung has precluded this valuable energy source from being applied to lung hyperthermia.

Thus, the need for a means of delivering safe, effective, and well-tolerated localized heating to lung tumors is clear. The invention solves this problem, in the preferred embodiment, by an unconventional use of "breathable liquids" (e.g., perfluorocarbon liquids) and therapeutic ultrasound.

As used herein, the phrase "breathable liquids" refers to liquids which have the ability to deliver oxygen into, and to remove carbon dioxide from, the pulmonary system (i.e., the lungs) of patients. Examples of breathable liquids include, but are not limited to, saline, silicone and vegetable oils, perfluorochemicals, and the like. One of the presently-preferred breathable liquids is perfluorocarbon liquids.

Perfluorocarbon (also referred to herein as "PFC") liquids are derived from common organic compounds by the replacement of all carbon-bound hydrogen atoms with fluorine atoms. They are clear, colorless, odorless, nonflammable, and essentially insoluble in water. They have extremely high dielectric strength and resistivity. They are denser than water and soft tissue, have low surface tension and, for the most part, low viscosity. Perfluorocarbon liquids appear to have the lowest sound speeds of all liquids and are also unique in their high affinity for gases, dissolving up to 20 times as much O<sub>2</sub> and over three times as much CO<sub>2</sub> as water. Like other highly inert carbon-fluorine materials which are widely used in medicine (e.g., in drugs, Teflon implants, blood oxygenator membranes, etc.), perfluorocarbon liquids are extremely nontoxic and biocompatible. For a review, see: Biro, P.B., and P. Blais, Perfluorocarbon blood substitutes, in CRC Critical Reviews in Oncology/Hematology, Vol. 6, No. 4, pp. 311-374, 1987.

To date, about 300 liquid compounds have been investigated for blood-gas exchange applications [4]. Those liquids which have evolved as artificial blood substitutes are complex perfluorocarbon liquid-based aqueous emulsions containing various chemical stabilizers and viscosity modifiers, along with conventional parenteral additives (glucose, electrolytes, starch, and buffers). Compatibility with blood and a surprising lack of major adverse effects have been demonstrated in several animal

species. The first administration of perfluorocarbon liquid blood substitute (Fluosol<sup>\*</sup>-DA, one of four commercial blood substitutes now available) to human volunteers occurred in 1978 [10], with the first clinical use taking place shortly after in 1979 [11,12]. Subsequently, numerous other studies have been carried out in Japan, the United States, Canada, and Europe that have confirmed the comparatively benign impact of infusing significant amounts (some tests used liters) of the perfluorocarbon/water emulsions directly into the systemic blood circulation [13,14,15]. The blood substitutes are not yet ready for general clinical systemic use for two reasons: a) the requirement to form an emulsion to suspend the perfluorocarbon particles significantly reduces the volume fraction of the gas carrier (the perfluorocarbon), thus large volumes must be infused, and b) the emulsion gradually coalesces as it circulates, leading to premature removal of many of the synthetic constituents from the blood. However, studies are currently ongoing in a number of clinically related therapeutic perfluorocarbon applications primarily taking advantage of the oxygen carrying capacity of blood substitute emulsions [16,17,18,19].

It was first demonstrated that mammals submerged in hyperoxygenated saline could breathe liquid and successfully resume gas breathing in 1962 [20]. However, this approach to liquid ventilation (LV) was eventually abandoned, due to the practical difficulties of dissolving sufficient quantities of O<sub>2</sub> in saline (done under high pressure), and because saline rinses away much of the surfactant lining the lung alveoli [21]. These problems were overcome in 1966, by Dr. Leland Clark [22], who was the first to use perfluorocarbon liquids (now oxygenated at atmospheric pressure) to support the respiration of mice, cats, and puppies. The extreme biocompatibility and suitable properties of certain perfluorocarbon liquids has

\* Trade mark

subsequently led to a significant body of ongoing research yielding promising clinical applications.

To date it has been clearly established that mammals can breathe (total ventilation support) oxygenated  
5 perfluorocarbon liquids for long periods (> 3 hours) and return to gas breathing without untoward long-term effects [23, 24]. In addition, studies have also shown that no adverse morphological, biochemical, or histological effects are seen after perfluorocarbon ventilation [24, 25, 26].

10 Perfluorocarbon liquids have also been investigated for lung lavage (washing) [27], and have been found to be effective for rinsing out congestive materials associated with Respiratory Distress syndrome (RDS) in adult humans [28]. While total respiratory support of both lungs via  
15 perfluorocarbon liquids is not without side effects, they are minor and transient (mild acidosis, lower blood  $PO_2$ , and increased pulmonary vascular resistance and decreased lung compliance) [3,29,30,31]. Other biomedical applications of perfluorocarbon liquid ventilation have also  
20 received serious research effort [32,33].

Pertinent to convective lung hyperthermia, i.e., lung heating by the repetitious infusion and removal of hot liquids to and from the lung, studies of the physiological heat exchange occurring from high- and low-temperature  
25 perfluorocarbon ventilation of animals have also been performed [30,41,42]. These studies have involved complete-lung liquid heating and cooling, and have been done at only moderate temperatures, but have illuminated and quantified many relevant physiological responses and  
30 systemic temperature effects. A very recent study [43] reporting hyperthermic (to 45°C) convection heating of lungs involved sustained heating of surgically isolated dog lung lobes via heated blood perfusion, i.e., heating induced from the blood side rather than the airway side.  
35 Taking measurements of lung edema, compliance, perfusion pressure, and serotonin uptake during 2-hour sustained

hyperthermia (done at 37.6°, 40.7°, and 44.5°C, time-averaged lung temperatures), no significant changes in lung parameters were found other than expected increases in perfusion pressure with temperature. The authors conclude  
5 that a normal lung appears to tolerate well the sustained heating regimens appropriate for cancer hyperthermia applications.

However, the problem of how to effect controlled and sufficiently localized hyperthermia of malignant lung  
10 tissue has, until now, remained unsolved.

As stated earlier, one way of treating pulmonary-related diseases, conditions and/or abnormalities is by the implementation of chemotherapeutic agents, either alone or in conjunction with other therapeutic techniques (e.g.,  
15 radiotherapy). However, there are many problems existing when employing conventional techniques of chemotherapy. For example, in the presence of lung disease and intrapulmonary shunting, systemically administered drugs are ineffectually delivered to the diseased portion of the lung.

One conventional method of introducing such agents  
20 into a patient's pulmonary system consists of interrupting ventilatory support and exposing the delicate lung tissues of the pulmonary system to higher, and potentially traumatizing, pressures needed for manually delivering the agents. When practicing many of the conventional chemotherapeutic  
25 techniques, the final distribution of the agents, throughout the patient's pulmonary system, is generally non-uniform and typically "patchy".

Another problem associated with the presently-  
30 practiced methods of chemotherapeutic treatment of pulmonary-related diseases, conditions and/or abnormalities is often encountered during intensive care life support procedures. During such procedures, conventional gas ventilation is employed to maintain lung stability and to  
35 prevent lung collapse. However, the deleterious consequences of such life support procedures often precludes

successful weaning from the particular life support system back to pulmonary gas exchange. As such, the practice of chemotherapeutic treatment, in conjunction with such conventional life support systems and/or procedures, is  
5 severely hampered.

As exemplified above, there are significant problems which exist with conventional chemotherapeutic techniques of treating pulmonary-related diseases, conditions and/or abnormalities. Until this invention, these  
10 problems were unsolved.

#### Summary of the Invention

The invention provides, in one embodiment, a hyperthermic treatment of lung cancer, which includes the steps of: temporarily filling with a liquid medium pre-  
15 selected pulmonary air passages adjoining pulmonary tissues containing malignant cells, circulating exogenously heated liquid medium having a temperature in the range of from about 41° to about 50°C (preferably from about 42° to about 45°C) through the liquid-filled pulmonary air passages for  
20 a predetermined period of time, and thereafter removing the liquid medium from the pulmonary air passages of the patient. The liquid medium may be a perfluorocarbon liquid or physiological saline solution. Suitable perfluorocarbon liquids having the requisite physical and thermal proper-  
25 ties are characterized by an average molecular weight in the range of from about 350 to about 560 and by having: a viscosity less than about 5 CP at 25°C, a density less than about 2.0 g/cm<sup>3</sup> at 25°C, a boiling point greater than about 55°C, a vapor pressure in the range of from about 20 Torr  
30 to about 200 Torr, and a Prandtl number less than about 10 at 25°C. Representatives of such perfluorocarbon liquids are FC-84, FC-72, RM-82, FC-75, RM-101, and perfluorodecalin. The preferred group of perfluorocarbon liquids is characterized by having an average molecular weight in the  
35 range of from about 420 to about 460, a vapor pressure less

than about 100 Torr at 25°C, and a surface tension less than about 17 dynes/cm at 25°C.

The invention provides in another embodiment a hyperthermic treatment of lung cancer using ultrasound, including the steps of: temporarily filling with a liquid medium preselected pulmonary air passages adjoining pulmonary tissues comprising malignant cells, heating the adjoining pulmonary tissues comprising the malignant cells to a temperature in the range of from about 41° to about 50°C (preferably from about 42° to about 45°C) for a predetermined period of time by transmitting ultrasound through the liquid-filled pulmonary air passages, and thereafter removing the liquid medium from the pulmonary air passages of the patient. Perfluorocarbon liquids having the requisite physical, thermal, and acoustic properties for this ultrasound treatment are characterized by an average molecular weight in the range of from about 400 to about 560. Such perfluorocarbon liquids are also characterized by having: viscosity less than about 5 CP at 25°C, density less than about 2.0 g/cm<sup>3</sup> at 25°C, boiling point greater than about 75°C, vapor pressure in the range of from about 25 Torr to about 100 Torr, surface tension below about 17 dynes/cm at 25°C, acoustic impedance in the range of from about 0.8 to about 1.6 MegaRayls at 37°C, and acoustic attenuation less than about 1.2 dB/cm (at 1.0 MHz, 45°C, and acoustic intensity of about 3 W/cm<sup>2</sup>). The preferred group of perfluorocarbon liquids for this purpose is characterized by an average molecular weight in the range of from about 420 to about 460, and representative of these are FC-75, RM-101, and perfluorodecalin. Operable and preferred ultrasound frequency ranges are also disclosed, for use with different liquid-filled regions of the pulmonary air passages. The ultrasound may be produced by a transducer disposed within the liquid-filled pulmonary air passages, or the transducer may be disposed exogenous to the liquid-filled pulmonary air passages. For example,

the ultrasound may be transmitted through an intercostal space of the patient, or it may be transmitted from an exposed surface of the lung into the volume of same during an intra-operative application involving an "acoustic window" into the lung created by surgical means.

In yet another embodiment, the invention provides liquid infusion and isolation catheters, intracavitary ultrasound applicators, and intercostal ultrasound applicators for practicing the disclosed convection and/or ultrasound hyperthermia treatments of lung cancer.

In even another embodiment, the invention provides a means for delivering biologically active agents directly to at least a portion of the pulmonary system via liquid-born agents which are either recirculated in and out of the pulmonary system (e.g., by liquid lavage or liquid ventilation) or maintained static (i.e., non-recirculated) for extended periods of time. Breathable liquids are capable of providing, simultaneously, ventilation during drug delivery.

In still another embodiment, the invention provides a means to directly access cardiac output for drug infusion of biologically active agents, when systemic collapse precludes intravascular administration of such agents.

Other objects, aspects and embodiments of the invention will become apparent to those skilled in the art upon reading the following detailed description, when considered in conjunction with the accompanying drawings and the appended claims.

Detailed Description of the Preferred Embodiments

The invention provides, in one embodiment, a method of treating lung cancer by convection hyperthermia. Preselected pulmonary air passages that adjoin pulmonary tissues containing malignant cells are temporarily filled with a liquid medium such as physiological saline solution or, preferably, a perfluorocarbon liquid. By "pulmonary air passages" is meant the pulmonary channels, spaces or volumes in the trachea, left and right bronchi, bronchioles, and alveoli of the lungs that are normally occupied by air. In the practice of the invention, only the pulmonary air passages in contact with or near a patient's tumor site(s) are typically filled with the liquid medium, and gaseous ventilation of the remaining pulmonary air passages is maintained. Depending on the location of the lung cancer, as determined by available diagnostic methods, the fluid-filled pulmonary air passages may be localized in a lung, lobe or lung segment, and/or the bronchial tree may be selected for localized filling with the liquid medium. Localized filling of the pulmonary air passages in such a preselected manner can be effected by means of the representative infusion catheters described below. Diagnostic ultrasonic imaging can be used to monitor the filling of the pulmonary air passages, if either physiological saline or a perfluorocarbon liquid serves as the liquid medium. During the filling step, the perfluorocarbon liquid is preferably degassed at least 50%, and is most preferably substantially (almost totally) degassed.

To effect the localized convection hyperthermia treatment, exogenously heated liquid medium having a temperature in the range of from about 41° to about 50°C, and preferably from about 42° to about 45°C, is circulated through the liquid-filled pulmonary air passages for a period of time that may be determined at the discretion of the attending physician. During, prior to or subsequent to this hyperthermic treatment, the malignant cells may be

irradiated with ionizing radiation such as x-rays, electron beams, neutron beams, etc. To potentiate the effects of such radiation treatments, the liquid medium in the fluid-filled pulmonary air spaces may be oxygenated. In treatments where the preselected pulmonary air passages are initially filled with substantially degassed perfluorocarbon liquid, exogenously heated oxygenated perfluorocarbon liquid may be circulated into the liquid-filled pulmonary air passages after the filling process is complete, prior to and/or during irradiation of the malignant cells with the ionizing radiation.

The circulating liquid medium may also contain a biologically active agent, e.g., a therapeutic agent such as an anti-cancer drug (e.g., adriamycin), toxin, antibody-linked radionuclide, etc. In treatments where the adjunctive use of such water-soluble therapeutic agents is desirable, the liquid medium may be an aqueous perfluorocarbon liquid emulsion.

After the hyperthermic treatment period, which as mentioned will vary in a patient-specific manner, depending partly upon the tumor location and any adjunctive therapies employed, the liquid medium is removed from the pulmonary air passages of the patient.

A preferred liquid medium for this convection hyperthermia treatment is a perfluorocarbon liquid of the general type used for lung ventilation. Suitable perfluorocarbon liquids having the requisite thermal as well as physical properties for use in convection pulmonary hyperthermia include perfluorocarbon liquids characterized by an average molecular weight, of the perfluorocarbon constituent(s), in the range of from about 350 to about 560. Such perfluorocarbon liquids are alternatively characterized by having a viscosity less than about 5 CP at 25°C, a density less than about 2.0 g/cm<sup>3</sup> at 25°C, a boiling point greater than about 55°C, a vapor pressure greater than about 20 Torr but less than about 200 Torr at

25°C, a surface tension less than about 17 dyne/cm at 25°C, and a Prandtl number less than about 10 at 25°C. To provide some adjunctive respiratory support, and for use with radiation therapy, and to provide efficient lung  
5 filling in the degassed state, the perfluorocarbon liquid should also have an oxygen solubility greater than about 40ml/100ml. Representative perfluorocarbon liquids that meet the above criteria include FC-84, FC-72, RM-82, FC-75 (3M Company, Minneapolis, MN), RM-101 (MDI Corporation,  
10 Bridgeport, CN), dimethyladamantane (Sun Tech, Inc.), trimethylbicyclononane (Sun Tech, Inc.), and perfluorodecalin (Green Cross Corp., Japan). The preferred group of perfluorocarbon liquids, in terms of optimizing the operative combination of physical and thermal properties, are  
15 characterized by an average molecular weight in the range of from about 400 to about 460. Such perfluorocarbon liquids are characterized by having a vapor pressure less than about 100 Torr. The most preferred perfluorocarbon liquids have an average molecular weight in the range from  
20 about 420 to about 460, and representative of this group are FC-75, RM-101, and perfluorodecalin.

The invention also provides an ultrasonic hyperthermic treatment of lung cancer. In this embodiment, after the preselected pulmonary air passages adjoining the  
25 patient's malignant cells are filled with the liquid medium such that an adequate and appropriate acoustic transmission path has been established, the pulmonary tissues containing the malignant cells are heated to a temperature in the range of from about 41° to about 50°C by transmitting  
30 ultrasound through the liquid-filled pulmonary air passages. In a preferred embodiment, the ultrasound is produced by an intracavitary transducer that is positioned within the liquid-filled pulmonary air passages. Alternatively, the transducer may be located exogenous to the  
35 pulmonary air passages. For example, the ultrasound can be transmitted through an intercostal space between the ribs

of the patient, or the transducer can be applied to the pulmonary pleura or lung surface overlying the fluid-filled passages, following surgical displacement of ribs or other interfering tissues.

5           In order to serve as a suitable acoustical propagating medium in this ultrasonic hyperthermic treatment, the perfluorocarbon liquid should have the following physical, thermal, and acoustical properties: viscosity less than about 5 CP at 25°C, density less than about 2.0  
10 g/cm<sup>3</sup> at 25°C, boiling point greater than about 75°C, vapor pressure greater than about 25 Torr and less than about 100 Torr, acoustic impedance between about 0.8 to about 1.6 MegaRayls at 37°C, and acoustic attenuation less than about 1.2 dB/cm ( $\pm 20\%$ ) at 1.0 MHz, 45°C, and acoustic intensity  
15 of about 3 W/cm<sup>2</sup>. The perfluorocarbon liquid is preferably also characterized by an oxygen solubility greater than about 40ml/100ml. Perfluorocarbon liquids having an average molecular weight in the range of from about 400 to about 500 generally satisfy the above criteria, with the  
20 preferred group in terms of optimizing the thermal and acoustical properties having an average molecular weight in the range of from about 400 to about 460, and most preferably in the range of about 420 to about 460. Representative of this most preferred group of perfluorocarbon  
25 liquids are FC-75, RM-101, and perfluorodecalin.

      In treatments where the preselected liquid-filled pulmonary air spaces are localized in the bronchial tree, the ultrasound from an intracavitary transducer preferably has a frequency in the range of from about 250 KHz to about  
30 3 MHz, and most preferably from about 500 KHz to about 2 MHz. For peripheral lung treatments (i.e., in the membranous airways and alveoli of the lung), where the sound waves must necessarily traverse many more liquid-tissue interfaces, a lower ultrasound frequency in the range of  
35 from about 250 KHz to about 1.5 MHz is necessary when perfluorocarbon liquids serve as the liquid medium.

Ultrasound frequencies in the latter range are also recommended when the transducer is positioned exogenous to the lung.

The desired frequency within these ranges is established on the basis of the depth of heating sought. Lower frequencies are attenuated less and, therefore, are employed where deeper heating is preferred. Conversely, higher frequencies are more readily absorbed, and thus are more appropriate for more superficial heating. Optimal treatments may include a combination of the following strategies. First, a single transducer may broadcast at more than one frequency to effect a desired heating pattern. The changes in frequency in this case may be done by rapid incremental changes in frequency over a specified bandwidth using frequency modulation (FM) methods, or they may be done with serial changes over time whereby sound (in FM mode or not) is generated in predetermined frequency ranges for desired periods and then changed to other frequencies for periods of time. Second, multiple transducers (focused, diverging, or unfocused) may be employed to operate in tandem at similar or different frequencies (in FM mode or not) to effect desired heating patterns.

Where physiological saline serves as the liquid propagating medium, the ultrasound can be in the frequency range of from about 250 KHz to about 3 MHz from intracavitary transducers, and in the range of from about 500 KHz (preferably about 750 KHz) to about 3 MHz from exogenous transducers.

While the perfluorocarbon liquid is preferably degassed during the filling step, oxygenation of the liquid may be desirable (e.g., for radiation treatment or respiratory support) during the ultrasonic hyperthermic treatment. However, in order to suppress cavitation, the dissolved gas content (including oxygen, air, nitrogen, carbon dioxide or other gases) of the perfluorocarbon liquid in the liquid-filled pulmonary air passages should be held at

no more than about 75% of saturation for ultrasonic treatments in the 2-3 MHz range. No more than about 50% of saturation should be permitted for ultrasonic treatments in the 250 KHz to 1.5 MHz range. The requisite dissolved gas content can be maintained by circulating the perfluorocarbon liquid into and out of the lung during the treatment between the liquid-filled pulmonary air passages and an extraneous source of gas-content processing, such as a degassing chamber.

10           The invention also provides liquid infusion catheters, intracavitary ultrasound applicators, and exogenous ultrasound transducers, representative embodiments of which are shown in Figures 1-5. Prior bifurcated bronchial catheters that have been used for delivering liquid into a lung are not suitable for use in the subject convection and ultrasonic hyperthermia treatments, for a number of reasons. First, the subject treatments can be applied deeper in the lung than heretofore possible, and prior commercial devices lack sufficient flexibility and length to reach many of the segmented bronchi. In addition, the inflatable cuff material used in the prior devices tends to lose its structural integrity at the relatively high fluid temperatures involved in the subject treatments. Furthermore, the prior devices are in general too large in diameter to penetrate several of the pertinent segmental bronchial passageways in the lungs, and they also provide no instrumentation for monitoring local transient and steady state temperature, and pressure, and are ill-suited for positional information.

30           Referring initially to Figure 1, a representative embodiment of the subject liquid infusion and isolation catheter 20 is shown in conjunction with the pulmonary air passages 22 that lead to and ramify throughout the lungs 24. More particularly, catheter 20 is shown passing through the larynx 26 and trachea 28 and into a bronchus 30 and associated segmental bronchi 32.

Catheter 20 includes a flexible conduit 34 having a distal end 36 that is positioned, in this instance, within segmented bronchus 32, and a proximal end 38 that is positioned outside (or exogenous to) the patient. The representative embodiment shown in FIGURE 1 has a pair of inflatable cuffs 40 and 42 formed near the distal end 36 that are in fluid (liquid or gaseous) communication with corresponding channels 44 and 46 that exit the conduit 34 near the proximal end 38. Also shown at the proximal end 38, a liquid inlet/outlet connector 48 is in fluid communication through a liquid passageway 51 with an opening 50 at the distal end 36 of conduit 34. A gas ventilation channel 52 also is formed in the conduit 34 to be in fluid communication with a ventilation port 53 positioned so as to ventilate the bronchial tree. A pressure sensor 54 and temperature sensor 56 are positioned near the distal end 36, and have lead wires 58 and 60, respectively, passing through the conduit 34 and exiting at the proximal end 38. The temperature sensor 56 may take the form of a thermistor, thermocouple, resistance-based temperature device, etc. Suitable pressure sensors 54 include: solid-state piezoresistive diaphragm-based sensors, semiconductor strain gage sensors, etc.

The conduit 34 is typically formed from flexible plastics, such as a Teflon<sup>™</sup>, silicon rubber, polyurethanes, polyvinylchloride, Delrin<sup>™</sup>, or acetyl copolymers, or combinations thereof, having an outer thermal insulation layer 64 formed, for example, of a closed-cell plastic or rubber, to reduce heat loss to the tissues in contact with it, between the connector 48 and outlet 50 or at least the most proximal cuff 42. Alternatively, effective thermal insulation can be achieved by proper selection of the catheter material itself and its channel wall thicknesses. To minimize diameter and maximize flexibility, the conduit 34 is typically extruded to have the gas ventilation channel 52, the fluid channels 44 and 46, and the liquid

passageway 51 integrally formed therein. The above elements may alternatively be separately formed and bound in a common sheath (not shown), although this may disadvantageously affect the diameter and flexibility of the conduit 20.

5 The cuffs 40 and 42 are preferably constructed of polyurethane or other distensible material that will maintain structural integrity when stretched and yet not lose elasticity when subjected to high temperature liquids. 10 The cuffs 40 and 42 are concentrically formed about the conduit 34 to be selectively inflated and deflated via liquids such as physiological saline or perfluorocarbon liquids, or gas such as air, through the channels 44 and 46. A suitable connector 62, such as a Leur lock fitting, 15 is located at the terminal end of each channel 44 and 46 to provide attachment to a source of liquid or gas such as a lockable syringe or a hand or mechanical pump. In the circumstance whereby liquid is the preferred cuff inflation fluid, it is likely that some liquid will have been placed 20 in the cuff prior to use, to insure a gas-free volume inside the cuff. When inflated, the cuffs 40 and 42 bear against the encircling inner walls of the trachea 28, bronchus 30, and/or lobar or segmented bronchus 32 (depending upon the positioned location of catheter 20 in the 25 pulmonary air passages 22), in order to locally seal the lumen (3) of the airway(s) to prevent the passage of liquid and gas during the hyperthermic treatment. Although a pair of cuffs 40 and 42 are shown, one or both may be eliminated, e.g., if both lungs are to be filled with the 30 fluid. Additional cuffs may also be used to provide the requisite sealing. The number of cuffs used will depend on where the hyperthermic treatment is being directed in the lung, the passageways to be isolated and those to be kept gas ventilated, and the length of the catheter 20. In this 35 regard, the cuffs 40 and 42, when required, are sized according to their application, i.e., whether they will be

positioned in a large lobar bronchus (0.83 cm average diameter) or in a smaller segmental bronchus (0.56 cm average diameter). Cuffs sized to dam the main bronchi (1.22 cm average diameter) and trachea (1.8 cm average diameter) can also be readily fabricated. The use of two cuffs 40 and 42 in Figure 1 is for illustration purposes only and is not meant to imply that the untreated distal pulmonary segments 32 are to be unventilated by gas. In use, the catheter configuration(s) will be selected to reflect the requirement to gas ventilate untreated, air-filled portions of the lung.

The gas ventilation channel 52 is used to provide respiratory gas exchange to the portions of the lungs 24 not sealed off by the cuffs 40 and 42 or filled with the liquid. The channel 52 is preferably coupled to an appropriate machine, such as a mechanical ventilator, to supply gas through the port 53 formed in the wall of the conduit 34. In the absence of such a connection air ventilation may occur by the gas being drawn into channel 52 from room air by the natural respiratory motion of the lung.

The liquid connector 48 is attached to a liquid infusion system, such as described below. Briefly, such a system provides liquid for the desired treatment at a controlled but variable tidal volume and frequency, and at a controlled temperature and gas content. The pressure sensor 54 and the temperature sensor 56 positioned at the delivery end 36 permit monitoring of the temperature and pressure of the liquid within the liquid filled air passages. Additional sensors may be positioned at any point along the conduit 34 to permit comparative measurements and to permit flow rate information in the catheter to be obtained from dynamic measurements.

In use, the catheter 20 may be fitted with a rod (not shown) formed of bendable material, such as aluminum, that is bent, prior to insertion in most cases, to a configuration designed to guide the catheter 20 through the

trachea 28 to the desired location in the pulmonary air passageways 20. A fiber-optic assembly may be used either alone or in conjunction with the rod to provide visual confirmation of the positioning of the catheter 10. Such  
5 a fiber-optic assembly, including an optical fiber having a lens, may be integrated into or associated with the catheter 20, and coupled to a light source and an eyepiece to permit observation via video camera, still photographs, or the eye. A fiber-optic bronchoscope may be alternatively  
10 inserted through liquid passageway 51 for the same purpose. To assist in measuring distances to various parts of the lung, the outer surface of catheter 20 may be provided with distance indicator marks in spaced array.

Once the catheter 20 is in position, the various  
15 connectors at the proximal end are connected to the appropriate machines and monitoring devices. For instance, the liquid inlet/outlet connector 48 is attached to a liquid infusion system, and the fluid line connectors 62 are attached to suitable sources of liquid or gas. The cuffs  
20 40 and 42 are inflated as necessary to seal off the pulmonary air passages adjoining the cancer cells while maintaining gas communication to untreated lung volume. The gas ventilation channel 52 is hooked to a mechanical ventilator and a suitable gas mixture is supplied through  
25 the port 53 to the unaffected air passageways. With temperature and pressure being monitored, liquid from the infusion system is supplied through the liquid passageway 51 to the, in this instance, bronchiole 32 at a controlled frequency and tidal volume (indicated by arrow 51).  
30 Following the hyperthermic treatment, the liquid can be removed from the pulmonary passages 20 by suction, by gravity (i.e., placing the patient tilted with the head down in the so-called "Trendelenburg" posture), and by evaporation.

35 The liquid infusion and isolation catheter 20 may also be used in conjunction with external intercostal

ultrasound applicators to provide the means for liquid filling and to provide additional heating and/or cooling to the tumor site. For instance, as shown in FIGURE 2, a pair of intercostal applicators 66 and 68 are placed externally on the patient to direct sound waves between the ribs 70 and into the peripheral portions and bronchial spaces of the lung 24. These ultrasound power applicators 66 and 68 are composed of long aspect-ratio rectangular transducers 74, operated either singly or as a synchronous or asynchronous pairs. These applicators 66 and 68 can have flat (plane wave), broad-band unfocused transducers 74 or may have curved, focused transducers. Ideally these will be operated in the range from 250 KHz to 1 MHz.

Such applicators 66 and 68 can be used in conjunction with a liquid infusion and isolation catheter 20 to apply heat both convectively and ultrasonically to a specific portion of the lung 24. Although it would appear that a venetian blind or striped pattern of heating would result from this arrangement, it should be noted that the targeted tissue can be "scanned" up and down in front of the transducer array by a cyclic variation of the inflation pressure of the lung 24. This induced variation may be large or small, according to the motion desired. Likewise, the overall position of the tumor to be treated may be located with respect to the applicators 66 and 68 by virtue of inflation or deflation of the lung 24. Also, the respiratory motion normally present in the lung 24 may be suppressed by imposing a constant liquid infusion pressure at the desired level. Although not shown, it is to be understood that the applicators 66 and 68 may be in fixed position relative to each other, such as by mounting to a jig or frame.

Although not shown in this view, a transducer can alternatively be applied directly to the body of the lung following surgical resection of a rib or other interfering tissues. The transducer for this application will typical-

ly be supplied with a bolus of degassed coupling liquid, also serving the function of cooling the transducer and tissue surfaces.

Another method of providing ultrasound hyperthermia is to place an ultrasound applicator within the fluid-filled pulmonary air passage near the tumor to be treated. Figure 3 shows a representative embodiment of such an intracavitary applicator 76 for delivering an ultrasound transducer 78 to the treatment site. To facilitate the description, the reference numbers used in Figure 1 are correspondingly employed in Figure 3 (and in Figure 4, described below). The intracavitary applicator 76 of Figure 3 includes a conduit 80 having a distal end 82 positionable within the pulmonary air passages 22 and a proximal end 84 that remains outside the thoracic air passage 22. The conduit 80 encases a ventilation passageway 86 passing through the transducer 78 in fluid communication with the pulmonary air passages 22 through a distal opening 88. The passageway 86 terminates at the proximal end 84 of the conduit 80 with a coupling 90 for attachment to a respirator (not shown). The conduit 80 also houses a liquid inlet port 92, typically positioned distal to the transducer 78, and a liquid return port 94 positioned, in this instance, proximal to the transducer 78. The liquid inlet port 92 is in fluid communication with a liquid inlet coupler 96, and a liquid return port 94 is in fluid communication with a liquid return coupler 98, both couplers 96 and 98 being located at the proximal end 84 of the conduit 80. Formed concentrically about the ventilation passageway 86 and positioned distal to the transducer 78 and liquid ports 92 and 94 is an inflatable cuff 100. A fluid line coupling 102 is in fluid communication with the cuff 100, for connecting the cuff 100 to a suitable source of pressurized liquid or gas (e.g., air). Power cables 104 pass through the conduit 80 to provide high frequency electrical power to the transducer 78.

This conduit 80 is constructed with similar materials and by similar methods as the liquid infusion catheter 20 described above. Here, in Figure 3, the transducer assembly 78 is positioned concentrically around the ventilation passageway 86. In this manner, the distal cuff 100, when inflated, serves to dam the proximal pulmonary passages 30'. The distal cuff 100 also anchors the distal end 82 of the conduit 80, and thereby permits the transducer 78 to be manipulated into position in the center of the bronchus 30 (or trachea 28) to avoid contact with the bronchus wall 106 and the tumor 108. The cuff 100 is otherwise substantially the same as the cuffs 40 and 42 described above with respect to Figure 1. When the cuff 100 is inflated, it seals off the bronchus 30 so that a degassed liquid propagating medium 110 can be supplied to and fill the bronchus 30 through the liquid inlet port 92, to provide acoustic coupling and secondarily to cool the transducer assembly 78. Circulation of the liquid 110 may be accomplished by circulating liquid from the bronchus 30 through the liquid return port 94 to a liquid supply system, such as described below.

In order to prevent filling of the other lung, if that is desirable, an optional cuff plug 112, which is independent of the intracavitary transducer and its support shaft and conduit 80, is inserted within the other bronchus 30', and its degree of distension is controlled with pressurized liquid or gas supplied through a line 114. Respiration is accomplished through the one lung by supplying air through the ventilation passageway 86. Although not shown, it is to be understood that the cuff assembly 112 and 114 may, and preferably should, be supplied with a separate ventilation passageway (not shown) in order to ventilate the pulmonary air passage 32 distal to cuff plug 112. Pressure and temperature sensors (not shown) may also be disposed and used as desired, such as described above with respect to Figure 1. Installation of the intracavi-

tary applicator 76 can be accomplished substantially the same way as described above with respect to the liquid infusion and isolation catheter 20. Positioning of the transducer 78 with respect to the tumor 108 is accomplished by rotating the conduit 80 as shown by the rotational arrow 116.

The construction of such a representative intracavitary transducer assembly 78 is shown in greater detail in Figure 4. Here, one approach to providing selective directional heating patterns is illustrated. Figure 4 shows a thin-walled piezoelectric ceramic cylinder 180 that is longitudinally and circumferentially sectioned into four separate power transducers, with transducers 120 and 122 formed to have an arcuate cross-sectional shape of approximately  $120^\circ$ , as indicated by angle  $\theta$ ; and with transducers 124 and 126 formed to have an arcuate cross-sectional shape with an included angle of approximately  $240^\circ$ , as represented by angle  $\phi$ . Leads 128 supply power to the transducers, and the ventilation passageway 86 is shown, in this instance, passing coaxially through the cylinder 180. This multiple-transducer approach provides flexible heating patterns. For instance, with transducers 120 and 122 driven in parallel, a  $120^\circ$  pattern can be achieved. Similarly, with transducers 124 and 126 driven in parallel, a  $240^\circ$  heating pattern can be achieved. Finally, with all of the transducers being driven together, a full  $360^\circ$  of heating can be achieved along the length of the cylinder 180. Of course, full  $360^\circ$  heating patterns may also be achieved by cylindrical piezoelectric cylinders that are not sectioned.

Although the transducer assembly 78 is shown mounted coaxial with the conduit 80, it is to be understood that other positions and transducer configurations can be used. For instance, transducers formed of flat plates may be associated with or placed adjacent to the conduit 80 to radiate sound waves in one or more directions. Likewise,

the transducers 124 and 126 may be eliminated to leave only the transducers 120 and 122 mounted adjacent the conduit 80.

Figure 5 illustrates yet another representative embodiment of an intracavitary ultrasound applicator 130, in which a transducer assembly 132 positioned within a self-contained liquid-filled sac 134 for acoustic coupling and cooling. This applicator 130 includes a conduit 136 having a distal end 142 positioned within the bronchus 30 and a proximal end 144 positioned outside of the patient's body. A ventilation passageway 138 is formed within or associated with the conduit 130 having a ventilation port 140 formed approximately midway down the conduit 136 and an air line coupling 146 located at the proximal end 144 for attachment to a respirator (not shown). While not shown in this view, a ventilation passageway can also be provided to the distal end 142 if desired.

The conduit 136 also houses one or more liquid passageways that supply liquid from a liquid inlet coupling 148 to the distensible sac 134, and circulate liquid back to a liquid outlet coupling 150. The couplings 148 and 150 may be connected to a self-contained liquid supply system or a larger system containing a separate power supply circuitry and fluid flow module that circulates a degassed liquid at a controlled temperature for cooling the transducer assembly 132 and providing an acoustic coupling between the transducer assembly 132 and the pulmonary tissues and tumor 152. It is also possible to derive the coupling/cooling fluid from the liquid infusion system that supplies liquids to the lung. The sac 134 is constructed of a thin, pliable material, such as polyurethane, that readily conforms to the shape of an abutting pulmonary tissue or tumor to facilitate heating of the tumor. A fiber-optic assembly is shown as part of the applicator 130 having one or more optical fibers (not shown) passing through the liquid sac 134 and the transducer 132. The

fiber-optic assembly includes a lens 156 positioned on the distal end 142 of the conduit 136, an optical coupler 158 at the proximal end 144 to facilitate viewing through the lens 156 as previously described, and a light source that is supplied through cables 160 that also include power cables for the transducer assembly 132. A cuff 162 typically is formed on the conduit 80 distal to the transducer assembly 132, to be inflated and deflated through a cuff fluid line coupling 164 that is connected to a source of pressurized liquid or gas. This cuff 162 serves primarily an anchoring function, to assist and maintain acoustical positioning of the transducer 132 and liquid-filled sac 134 at the tumor site 152.

Both of the intracavitary applicators 76 and 130 described above can be positioned in the bronchial tree by first locating the tumor target via a flexible bronchoscope that indexes the lengths of the passageways and the position of the tumor. The applicator is then guided down the airways with the aid of a bendable rod, as described above. Such a rod is first bent slightly and then fed down one of the inner passageways of the applicator. The bend of the rod is sufficient to bend the distal end of the applicator in the desired direction. Supplementing this steering approach is a system of fiduciary marks taken from or correlated with the bronchoscope traversal that establishes the length required to descend down the airways. Finally, the fiber-optic assembly 154 can be used alone or in conjunction with the rod to accurately position the transducer assembly adjacent to the tumor to be treated.

The intracavitary applicator 130 may also be configured for hyperthermic treatment in other body cavities, e.g., the mouth, esophagus, uterus, or rectum, in which case a cuff may be provided for auxiliary anchoring purposes.

Figure 6 illustrates in greater detail a representative transducer assembly 132 for use in conjunction with

the distensible acoustic-coupling sac 134. Here, the conduit 136 is shown in cross section having a liquid inlet passageway 166 centrally positioned within a concentric liquid return passageway 168. The liquid 170 passes  
5 through a manifold 172 into the lumen of the sac 134 to distend the sac 134 and circulate around the transducers 174. The liquid 170 then passes through the manifold 172 and into the return passageway 168. The circulation of the liquid 170, which is normally degassed water, aids in  
10 cooling the transducers 174 and provides an acoustic coupling for the ultrasound waves 176. Although not shown, it is to be understood that cuff fluid lines and the fiber-optic assembly lines can be constructed to pass axially through the sac 134 and the transducers 174 to  
15 distal positions along the conduit 136.

Another embodiment of the invention provides a means for delivering biologically active agents, through the pulmonary air passages of a patient, for treating, controlling and/or diagnosing pulmonary and/or systemic,  
20 diseases, conditions and/or abnormalities. In this embodiment of the invention, the biologically active agents are delivered into at least a portion of the pulmonary system via the implementation of liquid lavage/ventilation of at least a portion of the patient's pulmonary air  
25 passages. Specifically, in this embodiment of the invention, biologically active agents are delivered into at least a portion of the patient's pulmonary system via liquid-borne agents which are either recirculated in and out of the preselected portion of the pulmonary air  
30 passages in a liquid lavage fashion or maintained static (non-recirculated) for extended periods of time. If breathable liquids are used, pulmonary delivery of biologically active agents can be performed with simultaneous pulmonary ventilation.

35 As used herein, the phrase "biologically active agents" refers not only to physiologically-active agents

(e.g., chemotherapeutic agents), but also to agents which may be physiologically inert but are nonetheless biologically active in that they are useful as e.g., diagnostic agents.

5       As used herein, the phrases "liquid lavage",  
"liquid ventilation", and/or "liquid lavage/ventilation"  
individually and collectively refer to gravity-assisted  
and/or mechanically-assisted passing of liquid mediums  
10       through at least a portion of a patient's pulmonary air  
passages. The liquid mediums being passed therethrough  
need not, necessarily be "breathable" (e.g., in those  
instances when a liquid lavage process is employed solely  
for washing/rinsing a portion of the lungs). However, when  
employed in liquid ventilation, it is preferable that the  
15       liquids have the ability of gas exchange.

      This embodiment of the invention, pertaining to the  
pulmonary administration of biologically active agents,  
provides a method for treating, controlling and/or  
diagnosing a patient's pulmonary-related diseases, condi-  
20       tions and/or abnormalities. This new method is especially  
useful when treating, controlling and/or diagnosing condi-  
tions wherein blood is preferentially shunted away from  
diseased pulmonary regions and, thereby, systemically  
delivered agents are at least partially precluded from  
25       reaching these regions. This embodiment is also useful as  
a means for introducing agents such as surfactants,  
steroids, antibiotic agents, chemotherapeutic agents,  
chemotactic agents, diagnostic agents, and the like,  
primarily, if not exclusively, into the pulmonary system,  
30       when systemic absorption of such agents is undesirable.

      The implementation of liquid lavage/ventilation  
techniques, as a vehicle for delivering biologically active  
agents to at least a portion of a patient's pulmonary  
system, is of particular importance for many reasons.  
35       Examples of some of the advantages associated with the pul-  
monary administration of biologically active agents

includes, but are not limited to, the following: (a) it results in the homogenous delivery of the agents throughout the pulmonary system for treating, controlling and/or diagnosing diffuse diseases, conditions and/or abnormalities, while simultaneously supporting gas exchange, if desired; and/or (2) it can be employed to selectively deliver biologically active agents to desired areas of the pulmonary system for treating controlling and/or diagnosing local diseases, conditions and/or abnormalities. In each of the aforementioned instances, the process of the selective pulmonary administration of biologically active agents minimizes normal, healthy, delicate pulmonary tissues from being exposed to toxic agents, such as is often encountered during conventional systemic chemotherapeutic and/or diagnostic techniques.

When practicing the embodiment pertaining to the pulmonary administration of biologically active agents, the agents, passing through at least a portion of the patient's pulmonary air passages, can react with, and/or diagnose, the patient's biological system in a number of ways. For example, the agents introduced in accordance with the invention, by pulmonary administration, may be used in the following ways: (a) to react directly on and/or diagnose the patient's pulmonary system, (b) to react on and/or diagnose both the patient's pulmonary and systemic system, and/or (c) to differentially react on and/or diagnose specified regions of the patient's pulmonary system.

Through research, it was discovered that there are many advantages of delivering biologically active agents directly to the surface of the pulmonary air passages (e.g. lungs) via liquid lavage/ventilation. Some of the more important advantages include, but are not limited to, the following:

1. The delivery of the desired biologically active agents directly through a patient's pulmonary air passages is enhanced by several

physiological principles, such as, for example, (a) the large exchange surface area of the lung (i.e., from about 50 to about 100 m<sup>2</sup>), (b) the entire cardiac output passes through the pulmonary capillary bed, (c) the thin barrier (i.e., alveolar wall thickness) and the short diffusion distances enhances absorption of the agent, and (d) the uniform distribution of low surface tension liquids throughout the pulmonary system.

2. In many cases, the action of the biologically active agents (e.g., surfactants to lower pulmonary surface tension, bronchodilators to relax airway smooth muscle, pulmonary vasodilators to increase pulmonary blood flow, steroids for lung inflammation, chemotactic agents, chemotherapeutic agents and/or diagnostic agents for lung cancer, and the like) are exclusively directed to a portion of the patient's pulmonary air passages (e.g., lungs) and would be undesirable in the rest of the body.

3. In diseased and/or abnormal lungs, a common problem is poor distribution of pulmonary blood flow and ventilation. This problem is obviated in the liquid-filled lung, in that liquid and blood flow are uniformly distributed and matched. This physiological principle enables efficient exchange of biologically active agents into a lung where exchange would otherwise be impossible.

4. Liquids can be selectively directed to specific regions of the patient's pulmonary air passages by a number of different conventional means, such as a bronchoscope, a conventional catheter or even a specialized catheter, similar to that employed in the hyperthermia treatment mentioned earlier. This capability of selectively

directing liquids comprising biologically active agents would be particularly useful when only a specific region of the patient's pulmonary system requires delivery of such agents (e.g., chemotherapeutic cancer drugs which may be harmful to normal, healthy lung and body tissue in high concentrations and agents which facilitate pulmonary debridement).

5  
10  
15  
5. In the case of systemic vascular compromise or shock, intravascular administration of agents is ineffective under conventional practices. However, the passage of the necessary biologically active agents through at least a portion of the patient's pulmonary air passages by liquid lavage/ventilation techniques provides a direct route for agent administration.

When practicing the embodiment of the invention pertaining to the pulmonary administration of biologically active agents, the selected liquid is augmented with the selected agents. These agents can be present in the liquid medium in any suitable form (e.g., bulk form, a suspension, a dispersion, a liquid form, an emulsion form, encapsulized and the like and/or combinations thereof). The particular form of the agent will depend upon many different variables (e.g., the specific agent being used, the area being treated and/or diagnosed, the condition and/or abnormality being treated, controlled and/or diagnosed, the parameters under which the liquid lavage/ventilation process is performed, etc.).

20  
25  
30  
35  
Moreover, the selected biologically active agents can be incorporated into the liquid medium by any suitable technique. Examples of suitable incorporation techniques include, but are not limited to, injection, blending, dissolving, employing conventional incorporation procedures and incorporation of specific incorporation procedures (see. e.g., Figure 38).

Any suitable biologically active agent can be employed when practicing this embodiment of the invention. Examples of suitable agents include, but are not limited to, anti-cancer agents, vasoconstrictors, vasodilators, bronchoconstrictors, bronchodilators, surfactants, steroids, antibiotic agents, chemotactic agents, toxins, antibody-linked radionuclides, diagnostic agents, contrast agents, and the like, and/or combinations thereof.

When employing vasoconstrictors, vasodilators, bronchoconstrictors and/or bronchodilators (e.g., epinephrine, acetylcholine, priscoline and sodium nitroprusside), they can be used in any suitable amount necessary to achieve the desired results, in view of the specific conditions, diseases and/or abnormalities present. For example, the amount of these biologically active agents can range from between about 0.001 to about 10.0 mg for each kilogram of body weight of the patient whose physiological conditions, diseases and/or abnormalities are being controlled, diagnosed and/or treated in accordance with this embodiment of the invention. In another instance, it may be desirable to have the amount of these biologically active agents range from between about 0.004 to about 7.0 mg/kg, or from between about 0.007 to about 4.0 mg/kg, or from between about 0.01 to about 1.0 mg/kg.

As indicated above, the amount of biologically active agent employed depends, in part, on the specific set of circumstances revolving around each individual case.

In addition to the above, this embodiment is particularly useful for delivering anti-cancer drugs (e.g., adriamycin), toxins, antibody-linked radionuclides, and the like and/or combinations thereof, to at least a portion of the patient's pulmonary system by being passed through the patient's pulmonary air passages.

Any suitable liquid can be used as the liquid carrier when practicing the embodiment pertaining to the pulmonary administration of biologically active agents. As

stated earlier, depending upon the specific circumstances, the liquid carrier need not be breathable. In most instances, however, the liquid carriers employed are breathable.

5        Particularly useful breathable liquids which can be used as the liquid carrier include, but are not limited to, perfluorochemicals, saline, silicone and vegetable oils, and the like. Of the aforementioned liquids perfluorochemicals (e.g., perfluorocarbon) liquids are presently preferred.  
10

      Some of the reasons for preferring perfluorochemicals include, but are not limited to, (a) they have a high solubility for respiratory gases, thereby being able to maintain ventilation during therapeutic and/or diagnostic  
15 procedures; (b) they have a low surface tension which facilitates the uniform distribution of the liquids and the biologically active agents throughout the pulmonary system; and/or (c) they are generally biologically inert, thus preventing possible side-effects due to the liquid  
20 carrier and the biologically active agent interacting. It should be noted, however, that other liquids can be preferred over perfluorochemicals, depending upon the specific circumstances and the desired results.

      There are a number of clinical conditions when  
25 liquid lavage (washing) of the pulmonary system is necessary to debride the alveolar surfaces of unwanted secretions, particles, toxins, etc. (e.g., alveolar proteinosis, cystic fibrosis, aspiration syndromes, and the like). Conventional lavage procedures generally employ the use of  
30 isotonic saline as the washing media since it is relatively non-damaging to the alveolar surface. However, because saline does not carry a substantial amount of oxygen to support respiration, only one lung can be washed at a time. The other lung is maintained with 100% oxygen. This  
35 imbalance usually results in hypoxia during and after conventional the lavage procedures.

In several research reports, it has been documented that it is possible to wash both lungs, simultaneously, if a breathable liquid (e.g., perfluorocarbon) is employed as the washing media. In view of the embodiment of the present invention pertaining to the pulmonary administration of biologically active agents, an extension of the concept which employs breathable liquids as the washing media, in a liquid lavage procedure, is to augment the breathable liquid with an effective solvent appropriate for the particular injury to the patient's pulmonary air passages. For example in the case of Adult Respiratory Distress Syndrome (also referred to herein as "ARDS"), the breathable liquid may contain a suspension of antiproteases to more effectively perform the following functions: (a) inhibit protein leakage, (b) wash out alveolar debris and (c) maintain gas exchange. Furthermore, in the case of aspiration syndromes, the breathable liquid may contain an agent to neutralize or buffer the action of the aspirant on the lung surface. For example, if the aspirant is of an acidic nature (e.g., gastric contents), the breathable liquid may be buffered with bicarbonate to balance the pH and minimize lung epithelial damage.

When practicing the embodiment of the invention, wherein the biologically active agents are introduced via a liquid lavage procedure, the liquid carrier (augmented with the desired active agents, whether in bulk, suspension, dispersion, emulsion and/or encapsulization form) can be placed in an inspiratory reservoir ( $R_I$ ). This inspiratory reservoir is generally suspended above the patient and is in open communication with at least a portion of the patient's pulmonary air passages. For example, two ends of a Y-piece can be used to interconnect the  $R_I$  with the patient's endotracheal tube.

Gas ventilation is generally interrupted when instilling the liquid functional residual capacity from the  $R_I$ . This residual capacity may contain at least a portion

of the desired biologically active agents. Gas and/or liquid ventilation is then resumed and/or initiated depending upon whether the process is (a) a total or partial ventilation, (b) a total or partial lavage with breathable liquid, or (c) a total or partial lavage with a non-breathable liquid. After the resumption and/or initiation of gas and/or liquid ventilation, tidal volumes of a liquid washing medium are passed through the patient's pulmonary air passages. These tidal volumes of liquid medium may contain at least a portion of the desired biologically active agents.

In liquid lavage techniques, the tidal volumes of liquid can be passed through the desired portion of the patient's pulmonary air passages via gravity assistance, mechanical assistance or a combination of both. Similarly during liquid lavage techniques, the liquids can be removed from pulmonary air passages via gravity and/or mechanical assistance. If a Y-piece is employed as described above, the expired liquids can pass through its remaining port and be deposited into an expiratory reservoir.

Although the residual capacity of liquid remains in the pulmonary air passages throughout the entire lavage/ventilation procedure, each tidal volume of liquid is held within the patient's lungs for a period of time necessary to achieve the desired results, while maintaining the necessary exchange of gases, if necessary. For example, the liquid can be retained in the patient's pulmonary system for a period of time ranging from between about 60 seconds to about 1 second. In most instances, however, it will not be necessary to retain the tidal volume liquid in the patient's pulmonary system for more than about 30 seconds.

Similarly, the frequency of the tidal volumes of liquid also depends upon the specific results desired.

On the other hand, when practicing the embodiment of the invention, wherein biologically active agents are

introduced via a liquid ventilation procedure, the liquid ventilation process can also be achieved using a gravity-assisted system and/or a mechanically-assisted system. In this procedure, breathable liquid is generally oxygenated to maintain the arterial oxygen tension ( $P_{aO_2}$ ) constant; and carbon dioxide ( $CO_2$ ) is generally scrubbed from the system. Thereafter, the  $pO_2$  and  $pCO_2$  of the liquid are typically sampled, analyzed and/or controlled during the ventilation process to ensure constant inspired gas tensions and drug delivery levels. It should be noted that the augmentation of the liquid carrier with the biologically active agents can be performed either before, during and/or after the liquid is oxygenated.

Once the patient is connected to the liquid ventilation system which is being used as the vehicle for the pulmonary delivery of biologically active agents, tidal volume ( $V_T$ ) and functional residual capacity (FRC) is preferably monitored and/or controlled. Generally, ventilation schemes will be initially adjusted for effective carbon dioxide elimination and maintenance of physiological arterial  $CO_2$  tension ( $P_{aCO_2}$ ). In addition to the above, breathing frequency ( $f$ ),  $V_T$  and FRC are also generally monitored and/or adjusted to obtain physiological  $P_{aO_2}$  and  $P_{aCO_2}$ .

Regardless of whether a liquid lavage and/or ventilation technique is employed as the vehicle for carrying biologically active agents to the patient's pulmonary system via the patient's pulmonary air passages, heart rate, arterial pressure, hemoglobin-oxygen saturation, arterial blood gas tensions, and/or pulmonary function are generally evaluated before and during the process.

When practicing the embodiment of the invention pertaining to the pulmonary administration of biologically active agents via liquid lavage/ventilation, the liquid medium can be heated or cooled to temperatures above or

below the patient's normal body temperature depending,  
again, on the specific conditions and/or desired results.  
For example, in addition to the liquid medium being at our  
about the patient's normal body temperature, it can also be  
5 greater or less than that temperature.

For example, the temperature of the liquid medium,  
either before and/or during the liquid lavage/ventilation  
process, can range from between about the normal body  
temperature of the patient whose physiological conditions,  
10 diseases and/or abnormalities are being diagnosed, controlled and/or treated to about 20% above the patient's  
normal body temperature. Generally, if such a hyperthermic  
treatment is desired, the temperature of the liquid medium  
can range from about the patient's normal body temperature  
15 to about 15% greater than the patient's normal body temperature, or from about the patient's normal body temperature to a temperature about 10% greater than the patient's  
normal body temperature, or from about the patient's normal  
body temperature to a temperature about 5% greater than the  
20 patient's normal body temperature, or from about the  
patient's normal body temperature to a temperature about  
1% greater than the patient's normal body temperature. In  
each instance, the liquid medium's temperature will depend  
upon the specific circumstances present and the results  
25 desired.

Moreover, the temperature of the liquid medium,  
either before and/or during the liquid lavage/ventilation  
process, can range from between about the normal body  
temperature of the patient whose physiological conditions,  
30 diseases and/or abnormalities are being diagnosed, controlled and/or treated to about 20% below the patient's  
normal body temperature. Generally, if such a hypothermic  
treatment is desired, the temperature of the liquid medium  
can range from about the patient's normal body temperature  
35 to about 15% less than the patient's normal body temperature, or from about the patient's normal body temperature

to a temperature about 10% less than the patient's normal body temperature, or from about the patient's normal body temperature to a temperature about 5% less than the patient's normal body temperature, or from about the patient's normal body temperature to a temperature about 1% less than the patient's normal body temperature. As above, the temperature of the liquid medium will depend upon the specific set of circumstances present and the results desired.

10 In addition to the above, it is also within the scope of this invention for the liquid medium's temperature, either before and/or during the liquid lavage/ventilation, to range from between about 10% below to about 10% above the normal body temperature of the patient whose  
15 physiological conditions, diseases and/or abnormalities are being diagnosed, controlled and/or treated. In other instances, however, it may be desirable to have the temperature of the liquid medium range from between about 5% below to about 5% above the patient's normal body temperature, or from between about 3% below to about 3% above the  
20 patient's normal body temperature, or from between about 1% below to about 1% above the patient's normal body temperature.

25 When practicing the embodiment pertaining to the pulmonary delivery of biologically active agents, the particular temperature range of the liquid medium, either before and/or during the liquid lavage/ventilation, will depend upon the desired results and specific circumstances of each individual implementation.

30 As stated earlier, the embodiment of the invention, pertaining to the pulmonary administration of biologically active agents, is especially useful for treating certain types of lung cancer. The phrase "lung cancer" as used herein, generally refers to tumors arising in major airways  
35 and pulmonary parenchyma.

Therapeutic treatment of lung cancer with chemotherapeutic agents (e.g., adriamycin, toxins, antibody-linked nuclides, etc.) may have devastating effects on systemic tissues when delivered at the high levels which  
5 are generally necessary for the treatment of many types of lung cancer.

On the other hand, the embodiment of the present invention, which employs liquid lavage/ventilation techniques for the pulmonary administration of biologically  
10 active agents, provides a successful means for delivering therapeutically high levels of anti-cancer agents to the lung surface (cancer site) relative to the systemic tissues, therefore minimizing adverse side effects.

Another pulmonary abnormality, which can be chemotherapeutically treated with the embodiment of the present  
15 invention pertaining to the pulmonary administration of biologically active agents, is respiratory distress syndrome. Respiratory distress syndrome is characterized in both neonate and adults by their inability to  
20 effectively exchange oxygen and carbon dioxide as a result of lung immaturity (infants only), damage, or a combination of both.

Because breathable liquids, such as perfluorocarbons, have low surface tensions and high solubilities  
25 for respiratory gases, when practicing the present invention, such liquids can be used to homogeneously expand the lung with low pressures, while simultaneously supporting gas exchange and delivering biologically active agents to regions of the lung which are generally not accessible by  
30 systemic circulation. In comparison to existing conventional procedures for treating respiratory distress syndrome, the approach employed when practicing the present invention significantly reduces the risk of pulmonary damage.

35 Particular therapeutic agents which would be applicable in the treatment of respiratory distress syn-

drome (RDS) include, but are not limited to: exogenous surfactants, antibiotics, steroids, antioxidants, antiproteases, bicarbonate and the like. While all of these agents have proven clinical applicability for treatment of RDS, they have significant limitations associated with their conventional means of delivery. However, the pulmonary administration of these agents, in accordance with the practices of the present invention, (a) provides a means for overcoming most of the limitations encountered by conventional administration techniques and (b) effectively delivers the aforementioned agents to the injured/abnormal regions of the patient's pulmonary system. Moreover, due to the evaporative characteristics of many breathable liquids, practicing the present invention in this manner provides a means for assured deposition of these agents onto the lung surface, without residual interference due to the liquid carrier.

Yet another process, wherein the embodiment of the invention pertaining to the pulmonary administration of biologically active agents can be employed, is in Airway Smooth Muscle (ASM) Control. In addition to controlling pulmonary vascular smooth muscle for pulmonary circulation, by practicing the present invention, it is now possible to augment certain breathable liquids (e.g., perfluorocarbons) with therapeutic agents which control ASM and, therefore, airway resistance to flow.

In the case of severe asthma, the ASM contracts such that respiration is impeded and hypoxia and hypercapnia generally results. We have demonstrated that the addition of a ASM agonist and antagonist to a breathable liquid can significantly alter ASM tone and, subsequently, affect ventilating pressures. Specifically, in Example 12 of this invention (infra), acetylcholine was injected into a perfluorocarbon liquid during inspiration. As that Example demonstrates, there was a rapid increase in tracheal pressure due to airway constriction. Airway dilation,

on the other had, has also been demonstrated with the addition of other biologically active agents, such as isoproterenol and epinephrine, to a perfluorocarbon ventilation liquid.

5           The embodiment of the invention pertaining to the pulmonary delivery of biologically active agents can also be useful for diagnosing particular conditions, diseases and/or abnormalities in the pulmonary system. For example, contrast agents (e.g., radioopaque agents) can be augmented  
10 into the liquid medium to enhance structural delineation of the patient's pulmonary air passages. Moreover, agents which can evaluate diffusional barriers, pulmonary blood flow, and/or distribution of ventilation can also be employed.

15           The embodiment of the invention pertaining to the pulmonary delivery of biologically active agents can be employed with any technique wherein liquids are passed through, and/or retained in, at least a portion of a patient's pulmonary air passages for a period of time.  
20 Examples of such uses, wherein liquids are employed within the pulmonary system to treat, diagnose and/or control certain physiological conditions, diseases and/or abnormalities, include, but are not limited to, the following:

25           I.   Mechanical effects of Ultrasound:   This category pertains to the use of ultrasound to produce localized mechanical (non-thermal) effects of liquid-filled pulmonary spaces. Ultrasound beams can be focused or scanned on portions of pulmonary tissue (intercostally,  
30 intracavitarily, or intra-operatively) to take advantage of non-thermal effects. By employing appropriate powers and frequencies (typically lower than those used for hyperthermia) ultrasound can be used to agitate and mechanically stir (through a phenomenon termed "acoustic streaming")  
35 local regions of the liquid in the pulmonary air spaces, liquid which is in intimate contact with lung tissue, and

- 5 which may or may not be carrying the drugs. These mechanical effects can, by inducing localized convective motion in the fluid (on a scale varying from tracheal to alveolar characteristic dimensions), a) enhance drug transport in and to the lung, b) improve the flushing of substances out of the lung when using lavage, c) breakup "plugged regions" of the airways by inducing high frequency oscillations in the liquid and in movable substances (e.g., mucus, proteinaceous fluids, inhaled particulates, etc.)

II. Non-cancer Hyperthermia: This category pertains to ultrasound hyperthermia (e.g., employing the ultrasound methods and devices previously outlined for cancer treatment) for non-lung cancer applications. 5 Examples of such uses, include, but are not limited to, (a) the production of localized drug action caused by higher local temperatures at desired locations, and/or (b) making substances which are blocking airways less viscous by heating, and thus enhancing their removal (e.g., by 10 lavage) with or without mechanical effects of ultrasound being exploited.

When practicing any embodiment of the invention, it is generally necessary to monitor and/or control certain mechanical and/or physiological parameters. The particular 15 parameters which would fall into this category will depend greatly upon specific circumstances surrounding the specific application. Examples of variables which are generally taken into consideration when practicing the invention include, but are not limited to: the technique being 20 employed for liquid ventilation/lavage, the particular pulmonary condition being treated, diagnosed and/or controlled the particular method of treating, diagnosing and/or controlling the particular condition, and the likes and/or any combination thereof.

25 Parameters which are most often monitored and/or controlled generally can be divided into three categories. The first category includes the monitoring and/or control of parameters, such as breathing frequency, inspiratory and expiratory times, volume, flow rate, and/or pressure. The 30 second category includes the monitoring and/or control of parameters, such as the temperature of the inspired liquid. The third category includes the monitoring and/or regulation of parameters, such as oxygen and carbon dioxide tensions of the inspired liquids. While the aforementioned 35 list of categories includes those parameters which are most

likely to be monitored and/or controlled, is not intended to be an exhaustive list.

As can be seen from the above disclosure, the pulmonary administration of biologically active agents through at least a portion of the patient's air passages is also a means to directly access cardiac output for the infusion of selected agents when systemic collapse precludes delivery via intravascular administration.

As stated earlier, any suitable technique can be employed to combine the selected biologically active agent and the selected liquid carrier.

Furthermore, it should also be understood that the embodiment of the invention pertaining to the pulmonary administration of biologically active agents also includes the administration of solid, insoluble agents. In these instances, for example, a liquid-solid phase may be formed by dispersing and/or suspending a fine powder of the selected agent in the liquid carrier.

The examples which follow are intended to assist in a further understanding of the invention. Particular materials employed, species, and conditions are intended to be illustrative of the invention and are not limitative of the reasonable scope thereof.

#### EXAMPLES

Based on the well-established biocompatibility of perfluorocarbon liquids, the issues most central to determining the feasibility of the disclosed convection and ultrasound hyperthermia techniques were those having to do with the fluid, thermal, and acoustic characteristics of perfluorocarbon liquids and lungs filled with perfluorocarbon liquids. Below, the general physical, thermal, and acoustic properties of candidate liquids are quantified in parameter ranges appropriate to lung heating, as confirmed by isolated lung and in vivo experiments. By employing perfluorocarbon liquids that meet the disclosed criteria,

we have demonstrated sustained and controlled convective and ultrasound hyperthermia in large animal lungs in vivo.

A thorough investigation of the requisite properties of candidate perfluorocarbon liquids was undertaken. From these studies, the most suitable class of liquids was selected for use in confirming animal research. As described below, perfluorocarbon liquids were found to exhibit interesting acoustic properties leading to unexpected but, for the most part, favorable behavior for the purpose of liquid-filled lung ultrasound hyperthermia (LLUH). Chief among the findings are: a) pure perfluorocarbon liquids show measurable nonlinear acoustical behavior in intensity ranges suitable to LLUH ( $< 2 \text{ W/cm}^2$  @ 1 MHz), i.e., attenuation increases with power as well as frequency; and b) perfluorocarbons in the lung exhibit significant acoustical scattering of the ultrasound beam. The implications these observations have on the LLUH devices include 1) the need for lower frequencies than are used in conventional superficial ultrasound hyperthermia, 2) a natural advantage exists whereby inherent acoustic beam profile "smoothing" (i.e., flattening of the nearfield diffraction peaks) occurs due to augmented scattering, and 3) a potential benefit favoring focused ultrasound devices may exist in that preferential absorption in their focal regions should result from the nonlinear properties of these particular liquids. In addition, the physical properties of perfluorocarbon liquids have yielded some unexpected advantages. Chief among these are a) the tremendous gas solubility of the liquids make them unique in their ability to quickly and completely fill lung tissue, an advantage important for acoustic coupling, and b) the high gas solubility can likely be exploited to suppress cavitation in the liquid. In addition, the low surface tensions of perfluorocarbon liquids, as shown in Figure 8, enhance the liquids' ability to readily fill the lung. Also, when a lung becomes filled with liquid, liquid

resides on both sides of the vascular spaces, that is, on both the gas side and the blood side. By regulating the amount of liquid infused into the lung space, the blood flow can be controlled. This is because the more fluid that is introduced, the more compressed the lung capillaries become. Reduced blood flow is an important mechanism to reduce heat dissipation and therefore to further localize the treatment to the desired target tissues. Also, the liquid distribution in the lung can be used to control the distribution of pulmonary blood flow.

A wide range of perfluorocarbon liquids were initially considered in an evaluation of physical, thermal, and acoustic properties for selecting the most apt liquids for liquid-filled lung procedures. A summary of these properties is described in detail below.

#### EXAMPLE 1

##### General Characteristics of Perfluorocarbon Liquids

Physical properties: The candidate perfluorocarbon liquids spanned a wide range of molecular weights, as indicated in Figure 7. For reference purposes, the physical properties of the liquids are presented in the Figures in order of molecular weight, with water properties included for comparison, and, unless otherwise stated, are measured at 25°C.

Fluid flow properties: The predominant force involved in lung inflation is the surface force along alveolar walls due to the action of surface tension effects from the moist lining of the alveoli. The introduction of bulk liquid into the lung significantly reduces these forces since the gas/liquid interface is removed. Further reducing these forces is the fact that perfluorocarbon liquids have some of the lowest surface tensions recorded for liquids (Figure 8). These combined effects means that the net pressure to maintain inflation in a PFC-filled lung is roughly 20-30% of that required for air inflation [61].

This fact is advantageous for providing cuff isolation of lung lobes and segments since cuff sealing in the airways can be accomplished with lower pressures than for normal clinical bronchial intubation.

5           Perfluorocarbon liquids are generally poor sol-  
vents, being essentially insoluble in water, alcohols, and  
most biologically active materials. This is a primary key  
as to why they are superior to saline as acoustic  
coupling/heat transfer fluids for liquid-filled lung  
10   ultrasound and convection hyperthermia treatments. This  
immiscibility ensures that the phospholipid surfactant  
(which maintains low surface tension in alveolar wall  
moisture) will not readily be washed out of the treated  
lung. This in turn minimizes the respiratory difficulty  
15   which might otherwise occur in a lung after returning to  
gas ventilation [62].

          To reduce liquid flow resistance into and out of  
the lung it is important to minimize the effects of viscous  
resistance. Figure 9 shows that some of the perfluoro-  
20   carbon liquids considered are relatively high in absolute  
viscosity, compared to water. On this basis, liquids with  
molecular weights (see Figure 7 for molecular weights)  
higher than F-Decalin (i.e., perfluorodecalin) become less  
desirable. Strictly considered, flow resistance is more  
25   closely related to the "kinematic viscosity" (absolute  
viscosity/density) than absolute viscosity, usually as  
expressed in the "Reynolds Number" [63]. Considering the  
higher densities of the liquids (Figure 10), it is found  
that those perfluorocarbon fluids with molecular weights  
30   below F-Decalin have flow resistance characteristics  
equivalent to or better than water.

Gas solubility: To illustrate the tremendous  
capability of perfluorocarbon liquids to absorb dissolved  
gases, Figure 11 shows the oxygen solubility of six per-  
35   fluorocarbon liquids in comparison with water. From the  
standpoint of exploiting this property to suppress cavita-

tion, to assist in lung filling, and, of course, to enable simultaneous lung ventilation during liquid-filled lung hyperthermic treatments (via ultrasound and/or convection), the perfluorocarbon fluids are all roughly equivalent, with a slight preference going to molecular weights below F-Decalin.

#### EXAMPLE 2

##### Thermal Properties of Perfluorocarbon Liquids

Thermodynamic properties: In ultrasound lung heating it will be undesirable to induce boiling in the coupling liquid since, at the very least, this will interrupt acoustic coupling. As shown in Figure 12, this criterion renders FC-72 a very poor liquid selection, and RM-82 and FC-84 less than optimum as well. In this category, RM-101 and FC-75 roughly match the boiling points of tissues, so they are acceptable, though not as appealing as the higher molecular weight fluids.

The efficient removal of perfluorocarbon liquid from the lung after liquid-filled lung hyperthermia treatments must be a leading consideration in designing the proposed therapies. The primary removal mechanisms for the bulk liquid will be first pumping or suctioning the fluid from the lung, permissibly followed by gravity-induced drainage (enhanced by the high densities of perfluorocarbons). The remainder of the fluid is then removed by evaporation. The facility with which a liquid evaporates is expressed by its vapor pressure; the higher the value, the more rapid the evaporation. As Figure 13 demonstrates, perfluorocarbon liquids with molecular weights above F-Decalin are clearly unacceptable from this standpoint. It is not surprising that the most favorable liquids in this category (FC-72, RM-82, and FC-84) are the same ones that were undesirable from a boiling point perspective, since the physical phenomena are the same.

Heat transfer properties: The ability to convectively transfer heat to the lung will be governed by the "Prandtl number" of the fluid, which defines the ratio of viscous diffusivity to thermal diffusivity, i.e., the ratio (specific heat) x (viscosity)/thermal conductivity [64]. Because the specific heat for perfluorocarbon liquids is virtually constant (0.25 J/g-C) and since their thermal conductivities only vary by about 20% ( $k_{ave} = 0.064$  W/m-C), a Prandtl number comparison is dominated by differences in viscosity (see Figure 9). Thus, from this standpoint, all fluids with molecular weights below F-Decalin are generally preferred and are approximately the same.

The ability to sustain constant temperatures in the lung is determined by the "thermal capacitance" of the fluid, or (density) x (specific heat). Again, because there is no variation in specific heat between the fluids, the more dense fluids will be those with higher thermal capacitances.

### EXAMPLE 3

Laboratory acoustic measurements: For the purpose of obtaining attenuation data over the range of physical parameters described, a special Perfluorocarbon Fluid Conditioning and Acoustic Measurement Flow System was constructed, as depicted schematically in Figure 14. This system permitted low volumes of perfluorocarbon liquid (< 1 liter) to be conditioned to any desired temperature and gas saturation level while exposing the liquid in a transparent fluid sample cell to ultrasound. The fluid sample cell featured thin membranes (1 mil Monokote) on the top and bottom surfaces, allowing virtually loss-free coupling of the sound to the cell via temperature-controlled degassed water. Sound attenuation was measured via the force balance method, which detects acoustic radiation pressure [65]. The sound traversed the sample cell and was then absorbed by an absorber plate suspended from a precision

load cell. The acoustic path length through the perfluorocarbon liquid was 5.0 cm. An adjustable-height base plate below the absorber was adjusted to reduce oscillations in the absorber through the action of viscous fluid damping. The radiation forces were recorded by a digital voltmeter connected to the load cell, with the voltage signals representing force automatically sent to a computer where the data was converted to acoustic power in Watts and stored for later analysis. To accommodate the need for frequencies below 1.0 MHz, both 250 and 500 KHz power transducers were constructed.

Cavitation is a complex function of temperature, fluid properties, fluid purity and cleanliness, ambient pressure, and gas content. For the purposes of this study, clean perfluorocarbon liquid was used and measured over a temperature range from 25° to 45°C and at gas saturations from a completely degassed state to 100% saturation using air, O<sub>2</sub>, and blood gas (7% O<sub>2</sub>, 7% CO<sub>2</sub>, balance N<sub>2</sub>). Cavitation thresholds were determined primarily by high-speed video camera recording, by still photography, and by visual inspection for bubble formation through the transparent sample cell walls. Sound speeds were measured by frequency-matched ultrasound transmitter/receiver transducer pairs separated by a known and fixed gap. A single-path, time-of-flight method of velocity measurement was employed using an oscilloscope.

Perfluorocarbon liquids have sound speeds which are among the lowest recorded for any liquids (Figure 15). To obtain efficient coupling of the beam into the perfluorocarbon liquid from either water or tissue, the liquid's acoustic impedance, (density) x (sound speed), should approximately match that of water and tissue. Whereas the sound velocities are indeed very low in perfluorocarbon liquids, their higher densities favor a good acoustic impedance match, as shown in Figure 16. Figure 17 shows comparative values of perfluorocarbon acoustic impedances.

Although FC-5311 shows an almost perfect match, this liquid is ill-suited for use in liquid-filled lung hyperthermic treatments on the basis of the physical properties discussed above. The remaining acoustic matching values, while not ideal, can provide good coupling of sound between water and tissue. For example, the transmission loss of sound passing from water into FC-75 is only slightly over 3 percent.

#### EXAMPLE 4

##### Acoustic Properties of Perfluorocarbon Liquids

Acoustic measurement materials and methods:  
Ultrasound transmission is primarily governed by attenuation in the perfluorocarbon liquids and, at relatively higher intensities, cavitation (i.e., creation of small bubbles by gases liberated out of solution). Lab measurements of sound speed, impedance, attenuation, and cavitation were done in several perfluorocarbon fluids over a temperature range from 25° to 45°C and at various gas saturations representative of conditions anticipated in liquid-filled lung hyperthermic treatments in a special Perfluorocarbon Fluid Conditioning and Acoustic Measurement Flow System (depicted schematically in Figure 18).

Blood perfusion in liquid-filled lungs is much lower than under normal physiological conditions, particularly when the lung tissue being treated is not simultaneously ventilated. In addition to enhancing the localization of the treatment, as discussed above, by virtue of reducing blood perfusion dissipation of thermal energy, the ultrasound power required for lung hyperthermia is surprisingly lower than might be appropriate for other vascularized tissue, e.g., muscle. The acoustic intensities employed for the evaluation of perfluorocarbon acoustic properties ranged from 0-3.5 W/cm<sup>2</sup> and are expected to fully encompass the range appropriate for lung heating. Somewhat higher output powers were used in the cavitation

evaluations. In addition, although properties were measured at frequencies of 0.25, 0.50, 0.90, 1.0, 1.1, and 2.25 MHz, only the range from 0.25 to 1.1 MHz was studied in detail due to the high attenuation associated with 2.25 MHz sound. The following observations were made.

Acoustic impedance: Perfluorocarbon liquids have sound speeds which are among the lowest recorded for any liquids. To obtain efficient coupling of the beam into the perfluorocarbon liquid from either water (or tissue), the liquid acoustic impedance, (density) x (sound speed), should approximately match that of water and tissue. Whereas the sound velocities are indeed very low in perfluorocarbon liquids, their high densities favor acoustic impedance matching, as shown in Figure 16 (perfluorocarbons listed according to molecular weight). For example, the transmission loss of sound passing from water to FC-75 is only slightly over 3 percent.

Acoustic attenuation: The most surprising acoustic characteristic of perfluorocarbon liquids was found to be their low threshold for exhibiting nonlinear behavior. Figure 19 shows the attenuation behavior of FC-75 by comparing the acoustic power transmitted through 5 cm of degassed water (virtually loss-free) versus that through FC-75 at 1.0 MHz. It can be seen that the attenuation gradually increases with power (electrical power is normalized by the transducer face area and expressed as Electrical "Intensity"), even over the moderate power levels required for lung heating. The liquid attenuation is, however, extremely sensitive to frequency. As shown in Figures 20 and 21, the attenuation and the degree of nonlinearity fall dramatically at lower frequencies, showing virtually loss-free behavior at 250 and 500 KHz (within the limits of accuracy of the measurement method). The attenuation in perfluorocarbon liquids also increases as the fluids are heated, as depicted in Figure 22. This is an interesting nonlinear aspect as well, for attenuation in

water and most fluids decrease with temperature, due to the reduction of viscosity. Although perfluorocarbon attenuation increases with temperature, the use of low frequencies can compensate, resulting in very low losses, as the 250 KHz, T=45°C data of Figure 23 show. Figure 24 compares the attenuation in three perfluorocarbon liquids representing a significant range of molecular weights.

Cavitation: While the bio-effects of acoustic cavitation are apparently tolerated in some therapeutic applications [55], in principle it will be better to avoid it in the liquid-filled lung. The data obtained in these experiments have shown that cavitation is likely to occur at ultrasound intensity levels only if the perfluorocarbon liquid is at or very near its saturation point in terms of dissolved gases (e.g., O<sub>2</sub> or blood gases). Thus, it will not be advisable to support respiration in the lung with 100% O<sub>2</sub> saturated liquids while using ultrasound heating. However, this does not preclude the use of incompletely gassed liquids (e.g., 75% saturation) for use in simultaneous ventilation with ultrasound hyperthermia.

Also, it should be emphasized that simultaneous 100% O<sub>2</sub> liquid ventilation support while convectively heating the lung is feasible. Figure 25 shows the power dissipation which occurs from cavitation in 100% saturated FC-75 over the hyperthermic temperature range. This data also indicates that no cavitation occurs in degassed liquids. Some variation of the threshold for cavitation in gas-saturated liquids was found as a function of frequency as well as of temperature.

It is important to stress that even slight degassing seems effective in suppressing cavitation at these intensities. This is probably due to the tremendous perfluorocarbon affinity for gases. Perfluorocarbons appear less prone to cavitation at equivalent saturations and intensities than water. The perfluorocarbon capacity to dissolve gases is so high, in fact, it is difficult to

cavitate liquids at the recommended ultrasound powers even a few percent below saturation, as seen in Figure 18 (where gas saturation is changed in small increments by changing liquid temperature). Because of both decreased lung perfusion during liquid-lung procedures and the large "gas sink" characteristics of perfluorocarbon liquids, it is plausible that the pulmonary circulation would take several minutes to saturate degassed perfluorocarbon liquids introduced into the lung, particularly considering that the partial pressure of  $H_2O$  vapor may preclude sufficient dissolved gas saturation conditions from occurring at all. Completely degassed liquids were used in the animal experiments (described below). The liquids were cycled into and out of the lung (several minutes apart) to maintain low liquid gas levels.

#### Summary

On the basis of the foregoing experimental observations, the fluorocarbon liquids FC-75 (a mixture of perfluorobutyltetrahydrofuran and perfluoropropyltetrahydropyran; 3M Company, Minneapolis, MN) and RM-101 (a mixture of Furan, 2,2,3,3,4,4,5 heptafluorotetrahydro-5-(nonafluorobutyl) and 2H-Pyran, 2,2,3,3,4,4,5,5,6-nonafluorotetrahydro-6-(nonafluorodecafluoro); MDI Corp., Bridgeport, CN) were found equally suitable as ultrasound transmission and heat transfer fluids in the lung. Reinforcing the selection of these fluids (which, in purified form, should be substantially free of hydrogen) is the fact that both have been used in animal liquid ventilation research and have excellent records of biocompatibility [3]. FC-75 and RM-101 are thus considered representative of the class of perfluorocarbon liquids, most suitable for liquid-filled lung convection and ultrasound procedures, having the most preferred physical, thermal, and acoustical parameters. Since FC-75 is representative of this class, the presenta-

tion of its properties will be emphasized from this point on.

#### EXAMPLE 5

##### Acoustic Properties of Perfluorocarbon-Filled Lungs

5           Animal model/study design: Due to their size and structure, adult sheep lungs are good pulmonary models. In the following animal experiments, five adult sheep were used in acute in vivo and in vitro studies. A narrow band, 1.0-MHz, 6-cm diameter piezo-ceramic disk transducer with  
10           an integral temperature controlled coolant/coupling liquid was utilized for these studies. Both thermal techniques (measuring specific absorption rates (SAR) of power) and acoustic methods (measuring acoustic pressures and intensities) were employed. The animal preparation and experimental methods employed for the in vivo studies are described in detail below.

Animal Preparation: Following the methods normally used in ongoing liquid ventilation research, the animals were all initially given pentobarbital sodium (20 mg/kg) to  
20           induce deep sedation. After a local infiltration of 1% lidocaine in the neck, the right carotid artery and right jugular vein were cannulated. A tracheotomy was performed for the placement of either an endotracheal tube or a liquid infusion catheter (the catheter shown in Figure 1  
25           could be used for this purpose). To maintain biological stability, the sheep's untreated lungs are ventilated on a mechanical ventilator at a volume of 500 ml, at a frequency of approximately 15-20 breaths per minute, under skeletal muscle paralysis (pancuronium bromide; initial bolus of 0.1  
30           mg/kg, followed by 0.1 mg/kg/hr). In addition, steady state maintenance of the animals included an intravenous crystalloid infusion (10% dextrose with 10 mEq sodium bicarbonate and 1 mg sodium pentobarbital/100 ml fluid) administered at a rate of 3 ml/kg/hr. Physiological  
35           monitoring was done via arterial blood gas tensions, pH,

heart rate, and blood pressure measurements. Additional surgical procedures during in vivo experiments included double or triple rib resections, to expose an acoustic window for the ultrasound applicator. Also, small needle thermometry probes were inserted in deep muscle and in the isolated region of the lungs (described below). All animals were euthanized with magnesium chloride.

Liquid-filled lung procedures: To quantify acoustic properties in perfluorocarbon-filled lungs in vitro, a series of experiments were performed on isolated adult sheep lungs. There is a striking visual difference between a normal air-filled lung and one which is filled with fluorocarbon liquid. The glistening dark red color characteristic of the successfully filled "liquid lung" was one measure of a lung reaching complete filling. In addition, measurements of acoustic propagation were also used to confirm the degree of filling. It was found, both in the in vitro and in vivo cases, that the lung filling process could be accomplished in about one-quarter of the time previously required for perfluorocarbons if the liquid were completely degassed prior to the initial infusion (only 1-3 minutes). The enhanced filling process was due to the perfluorocarbons' ability to dissolve great quantities of gas, rather than simply depend on displacing the trapped alveolar air. It was found that saline filling required much more time than for the fluorocarbons using partially degassed liquids.

In vitro ultrasound experimental materials and methods: In vitro ultrasound characterizations were performed with an applicator consisting of a narrow band 1.0-MHz, 6-cm piezo-ceramic disk transducer with temperature controlled coolant/coupling liquid continuously surrounding it. The system was capable of delivering 150 Watts of acoustic power, though these power levels were in excess of that required for fast warmup and certainly much

more than was required for stable steady state lung hyperthermia.

5 The isolated lungs were instrumented either with thermocouple probes (29 gauge) or with ultrasound hydrophones for thermal or acoustic determinations of attenuation, respectively. Acoustic gel was used to insure good coupling into the tissue. The thermal technique used was that of determining the Specific Absorption Rate (SAR) from the initial rate of temperature rise [66] at different  
10 depths in the lung. Ratios of SAR at the various depths yielded attenuation. The hydrophone measurements recorded dynamic pressure variations directly which were displayed on an oscilloscope. Squaring of the pressure data resulted in data proportional to intensity, which could then be  
15 translated to attenuation values for known acoustic path lengths.

In vivo liquid-lung ultrasound hyperthermia materials and methods: To provide efficient filling of the lung lobe, completely degassed FC-75 was introduced through a  
20 conventional clinical bifurcated bronchial catheter that permitted infusion of the selected lung lobe while sustaining gas ventilation in the remainder of the lung. The catheter was placed without benefit of a bronchoscope, so the correct placement had to be determined by verification  
25 of lung inflation motions in the desired lung segments. The perfluorocarbon liquid was introduced at room temperature and only infrequently circulated in and out. In most cases the cranial segment of the right apical lobe was chosen for selective heating, both in the ultrasound and  
30 the convective hyperthermia experiments.

These segments had inflated volumes of approximately 250-300 ml. An "acoustic window" to the lung segment was obtained by resection of portions of three ribs essentially analogous to an intraoperative hyperthermia treatment.  
35 The treated lung segment was partially exteriorized through the "window" to enable invasive thermometry of the

treated lung at different depths. The sound was propagated directly through coupling water and membrane into the lung. In most cases, the lung surface was cooled with 37°C coupling water.

5           In addition to heating data, in vivo acoustic measurements were also performed via the hydrophone method previously described. Continuous recording of relevant physiological parameters were performed throughout the experiments. These measurements included systolic and  
10   diastolic blood pressure (reduced to Mean Arterial Pressure), core temperature, heart rate, and respiration rate. Gas ventilation was maintained by a mechanical respirator. Cardiopulmonary stability was confirmed throughout the treatments by taking periodic blood samples for arterial  
15   pH,  $pO_2$ , and  $pCO_2$ .

In vitro ultrasound results: Figure 26 presents typical in vitro attenuation values for isolated lung of an adult sheep. The attenuation shows a significant increase with increasing frequency. Note also that the attenuation  
20   levels are higher in the liquid-filled lung than for the pure liquid. It is postulated that this augmented attenuation is mostly attributable to scattering from the refraction effects of the sound speed mismatch between the parenchymal tissue and the liquid (increased scattering is  
25   supported by the ultrasound imaging results as well). Because scattering increases the effective acoustic path length, a wave traverses and spreads the beam slightly, the near loss-free propagation for lower frequencies (e.g., 250 and 500 KHz; Figures 20, 21, and 23) in perfluorocarbon  
30   liquids is no doubt preferred to frequencies above 1 MHz for deeper hyperthermia. Lower frequency ultrasound should also exhibit significantly reduced scattering since the wavelength increases substantially (e.g., to 3-6 mm) in relation to the main scattering structures (i.e., bronchioles, diameters < 1 mm [56]).  
35

Figure 27 demonstrates that the liquid-filled lung acoustic properties are dominated by the presence of the liquid (this likely also holds true for the thermal properties). This data shows that the effective sound speeds measured (both in vivo and in vitro) are close to those of the pure liquid (dashed line). Note that connective tissue sound speeds are usually higher than those of blood and muscle.

#### EXAMPLE 6

##### In Vivo Acoustic Lung Hyperthermia

Employing the methods and protocols described in Example 5, sustained hyperthermia (42-45°C to about 4 cm depth for 30 minutes) was successfully accomplished in the two animals used for the tests. The temperature vs. depth histories which resulted are represented by Figure 28, which depicts the experiment employing the greatest number of temperature probes. In this case probes were located in the interstitial tissue along the beam central axis at depths of 0.5, 1.0, and 2.0 cm, and also at 3.0 cm but slightly off axis. In addition, an on-axis probe was placed on the distal surface of the lung segment (approximately 6 cm from the treatment surface) between the lung surface and a rubber mat (which also acted as an acoustic absorber). As shown, lung temperatures exceeded 43°C to approximately 3 cm depth, with acoustic penetration through the lung segment indicated by the high temperatures on the distal surface (effectively 6 cm deep). The close tracking of the 2 and 3 cm depth temperatures (again, not in line with each other) may have been due to refractive effects or differences in local perfusion. The lower temperature at the 0.5 cm site is due to the conductive cooling of the coupling water (at 37°C). The "thoracic cavity" core temperature probe was located near the treated segment in the cavity. The steady state power requirements in this

case ranged between 12 to 15 Watts, again indicative of low pulmonary perfusions due to the liquid presence.

Perfusion response of the liquid-filled lung: The ultrasound power levels required for steady state hyperthermia were unexpectedly low due to low blood flow levels in the heated lung. An analysis of the physiological mechanisms involved, however, indicates that the perfusion is suppressed due to the combined effects of: 1) increased pulmonary vascular resistance due to the presence of the liquid compressing alveolar capillaries, 2) the shunting of the pulmonary circulation to other areas of the lung from locally low  $pO_2$  (here from degassed liquids), and 3) to shunting from a low pH buildup in the lobe [29,30,31].

#### EXAMPLE 7

##### In Vivo Convective Lung Hyperthermia

Convection hyperthermia materials and methods:  
Using the large animal liquid ventilation (LALV) system of Temple University (Figure 29), heated, temperature-controlled FC-75 could be circulated in and out of lung lobes and segments isolated via the bifurcated bronchial catheter method as described above. The animal preparation was essentially the same as for the ultrasound experiments. In this way convective lung hyperthermia was successfully administered to the cranial segment of the right apical lung lobe. To instrument the lung so that temperature probes could be easily placed at known depths, the lung segment was partially exteriorized through a "window" created in the same manner as was done for the ultrasound experiments.

Figure 30 shows the temperature history data for the convective lung hyperthermia experiment. The setup period was used for establishing proper placement and sealing of the liquid delivery catheter, for proper temperature probe placement, and to assess the response of the lung to LLCH parameter changes. It was found that the very

thin wall ( $\approx 2$  mil) vinyl air cuffs on the available bifurcated catheters had very little structural integrity at the elevated liquid temperatures required of the hyperthermic treatment. As such, the catheters provided adequate, but not high quality, sealing. Although this had very little physiological impact (since the gas ventilation of the remaining lung was quite adequate), it did result in diminished heat transfer rates. The development of a suitable liquid delivery catheter was therefore mandated.

During the experiment, the heat transfer to the lung segment was varied by changing both the inspiratory liquid temperature ( $T_{ins}$ ) and the tidal volume ( $V_t$ ) under constant cycling (5 "breaths" per minute) conditions. Beginning with a low  $T_{ins}$ , low  $V_t$  condition ( $43^\circ\text{C}$ , 40 ml), it was found that temperatures in the therapeutic range slowly fell below hyperthermic values. Lung perfusion effectively cooled the lung under these conditions. However, increases in  $T_{ins}$  and  $V_t$  overcame this decline, bringing temperatures back up above  $45^\circ\text{C}$  ( $t = 60$  minutes). Once the lung has reached the desired therapeutic temperature, the  $T_{ins}$  and  $V_t$  settings were adjusted downward to maintain good steady state hyperthermia ( $t > 60$  min).

Noteworthy trends: First, the temperature probes in the center of the lung segment interstitium (spaced 2-3 cm apart) consistently were within  $0.5^\circ\text{C}$  of each other at the higher tidal flows ( $t > 60$  min), and were usually within  $1^\circ\text{C}$  of each other at the lower flows ( $t < 40$  min). Therefore, spatially uniform heating can readily be achieved and controlled via the tidal flow. Secondly, the rates of lung temperature increase shown during the experiment ( $\approx 0.25$  C/min) are much more sluggish than rates which should occur at similar  $T_{ins}$  values in a properly designed clinical device. This is due to the aforementioned compromised heat transfer from the leaky catheter cuff. Indeed, much higher rates were found during the setup period prior to cuff leakage ( $\approx 1$  C/min for  $t < 25$  min).

Lastly, it should be noted that steady state lung temperatures closely tracked  $T_{ins}$ , which was measured outside the animal in the liquid circuit. By placing a temperature sensor at the distal end of the catheter, at the entrance  
5 to the heated lung lobe or segment, the lung temperatures should be known with a high degree of certainty. This is significant in that there should be no need for invasive lung thermometry during the subject treatment.

#### EXAMPLE 8

##### 10 Ultrasound Imaging for Liquid-filled Lung Procedures

The presence of liquid in the lung theoretically makes possible the use of ultrasound imaging, both for viewing lung structures and for use in conjunction with the ultrasound and convection treatments. Both in vitro and in  
15 vivo ultrasound imaging experiments were performed on perfluorocarbon-filled lungs as part of the animal studies described above. The diagnostic imaging system was a commercial clinical system (Diasonics) capable of sector-scanned images at frequencies from 3 to 7 MHz. B-scan images were obtained on exteriorized perfluoro-  
20 carbon-filled lung lobes and on lung lobes viewed through the rib cage and intrathoracically.

Consistent with the ultrasound results discussed previously, it was found that the increased attenuation and scattering of the very high diagnostic frequencies (3-7  
25 MHz) rendered the diagnostic value of imaging deep lung structures through liquid-filled lung parenchyma poor. The imaging of structures through liquid-filled lung parenchyma may be the one area where saline-filling of lungs provides a distinct advantage (due to matched sound speeds).  
30

The foremost advantages of diagnostic ultrasound imaging in the present application are for monitoring the lung-filling process and for confirming the integrity of the acoustic path. This conclusion is based on the dis-

tinct ultrasound images which were obtained when lung lobes reached gas-free or near-gas-free states.

#### EXAMPLE 9

##### Liquid-Filled Lung Hyperthermia and Chemotherapy

5           The prospects for using perfluorocarbon liquids as drug delivery vehicles may be quite favorable since commercial examples of fluoropharmaceuticals are many and diverse [60]. In addition, simultaneous locally delivered anesthesia in the treated tissue should also be possible via  
10 liquid delivery (though systemic anesthetic effects may also result). Although anesthetic use is often contraindicated in hyperthermia for safety reasons, because the maximum temperature in the lung may be set by the clinician with confidence in the subject (especially convection)  
15 treatments, simultaneous anesthesia may be feasible in this procedure. Coincidentally, fluorine-containing inhalation anesthetics account for the largest volume of fluorocompounds sold for purposes that are nonindustrial [60].

#### EXAMPLE 10

##### 20    Ultrasound Intracavitary Applicator (ICA) Experiments

Figure 4 shows a schematic of a representative applicator head. A thin-walled piezoelectric ceramic cylinder ( $\approx 1.0$  MHz resonance) was longitudinally and circumferentially sectioned into four separate power  
25 transducers with  $120^\circ$  and  $240^\circ$  included angles, respectively. The multiple-transducer approach provided flexible heating patterns. In these studies transducers 120 and 122 were driven in parallel (forming a synchronous pair), as were 124 and 126. Depending upon whether each pair or both  
30 were driven, either  $120^\circ$ ,  $240^\circ$ , or a full  $360^\circ$  of heating could be achieved along the length of the cylinder. The transducers were mounted in an applicator with self-contained cooling and an integral water bolus for sound coupling, as depicted in Figure 6. The diameter of this

first engineering prototype ICA transducer was 16 mm. Smaller cylinders more suitable for bronchial applications, however, can be readily made.

5 The applicator was mounted on a long (1 meter), flexible tubular shaft which housed the inlet and exit flow channels to the coupling bolus, as well as the RF power cables to the transducer. The water coolant flow dissipated heat to a maximum power of 100 Watts. The flow system was also characterized for pressure drop vs. flow rate to assure that acceptable pressure drops could be maintained in the long, narrow coolant channels.

10 The ultrasound beam quality was mapped in an acoustic test tank, while the thermal performance of the device was evaluated in a specially constructed body cavity phantom. Figure 31 shows the acoustic intensity mapped (via hydrophone) in water along the axial direction (z) of the transducer, 2 cm from the surface and in the middle of the 240° arc of energized transducers 124 and 126. Figure 32 presents SAR patterns measured in tissue-equivalent cavity phantoms by needle thermocouple probes at five axial positions and several azimuthal angles (measured from the center of the 240° arc of transducers 124 and 126. Figure 33 shows the depth (radially outward) heating patterns in the phantom from the surface to 2 cm into the phantom tissue. The 100-Watt maximum power employed is more than will be needed for most applications.

#### EXAMPLE 11

##### Liquid-filled Lung Convection Hyperthermia (LLCH) System

30 Figure 34 schematically shows a representative LLCH system. The system is constructed under requirements applicable to clinical use. It is designed to maintain complete sterility of the liquids and catheters, and is modular and portable for convenient use in either a surgical theater or hyperthermia/oncology suite. The LLCH system provides heated, temperature-controlled perfluoro-

35

carbon liquid to the patient in either degassed or oxygenated form (partially degassed liquid states are also possible). To impose controlled lung temperatures and heat transfer rates, the tidal volume and "ventilation" frequency (cycling rate of the fluid into and out of the lung), and the input liquid temperature are controlled by the operator. To insure sterility, the unit employs roller-type peristaltic pumps which completely contain the liquid in sterile tubing. Similarly, valves, fluid fittings, and reservoirs are easily replaced and sterilizable, or disposable. The inspiratory and expiratory flows, system liquid temperatures and components status are monitored and controlled by a central computer. The computer serves as the operator console during treatment, recording and displaying LLCH system parameters and invasive temperature probe data, and is also a work station for data playback and post-treatment analyses.

#### EXAMPLE 12

##### Pulmonary Administration of Drugs:

##### Cardiovascular and Airway Smooth Muscle Effect

This Example demonstrates a technique for directly delivering biologically active agents (i.e., acetylcholine, epinephrine, priscoline, sodium bicarbonate and sodium nitroprusside) into a patient's cardiopulmonary system, via the patient's pulmonary air passages.

Using previously developed perfluorochemical (PFC) ventilation techniques, similar to those disclosed in Shaffer, A Brief Review: Liquid Ventilation, and Wolfson, et al., A Experimental Approach for the Study of Cardiopulmonary Physiology During Early Development, (see, notes 3 and 35, respectively, of literature citations, *infra*), pulmonary gas exchange and acid-base balance were maintained in anesthetized and tracheotomized young cats.

When testing the dose-dependency effect of the pulmonary administration of acetylcholine [ACh], the effect

after the administration of the drug (expressed as a percentage of the baseline), as a function of the concentration of the drug, was monitored.

5 Here, the ACh was dispersed in the PFC liquid medium. The initial amount of ACh dispersed in the PFC liquid was 0.01 mg per each kilogram of the laboratory animal's body weight.

10 The PFC/ACh liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

Each of the animals tested had at least one of the following parameters recorded before, during and after the pulmonary administration of the drug: (a) heart rate (bpm), (b) mean arterial pressure (mm Hg), and (c) tracheal pressure (cm water). The averages for each of these recorded parameters were then calculated, depending upon the number of cats tested. These calculated values are plotted on the graph in Figure 35.

20 In addition to the above, the following parameters were also monitored and/or controlled: tidal volume, inspiratory and expiratory liquid flow rate, arterial chemistry, pulmonary compliance and resistance, and/or breathing frequency.

25 The dosage of ACh was then incrementally increased from 0.01 mg/kg up to 1.0 mg/kg. For each incremental increase, the animals tested had at least one of the aforementioned parameters recorded before and after the pulmonary administration of the drug.

30 Also for each incremental increase, the averages for each recorded parameter were calculated and plotted on the graph in Figure 35.

35 Referring to Figure 35, the data plotted therein demonstrates that, as a function of increasing the concentration of ACh in the inspired PFC liquid, typical dose-dependent cholinergic responses to ACh showed progressive

decreases in mean arterial pressure (i.e., reflecting vasodilation) and heart rate, and a progressive increase in the peak tracheal pressure (i.e., reflecting bronchoconstriction).

5           Another way in which the effect of the pulmonary administration of ACh was tested was by monitoring carotid pressure, as a function of time, before, during and after the pulmonary administration of the drug.           Here, 0.6 mg/kg of ACh was dispersed in the PFC liquid medium. The  
10       PFC/ACh liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

          A tracing of the animal's carotid pressure, before, during and after the pulmonary administration of ACh,  
15       demonstrates, among other things, that (a) the carotid pressure decreased by about 40 mm Hg after the drug was administered; (b) the decrease in carotid pressure began almost instantaneously after the drug was administered; and  
20       (c) the total time necessary to decrease the carotid pressure by about 40 mm Hg was about 10 seconds.

          Yet another way in which the effect of the pulmonary administration of ACh was tested was by monitoring tracheal pressure, as a function of time, before, during and after the pulmonary administration of the drug.

25           Here, 0.6 mg/kg of ACh was dispersed in the PFC liquid medium. The PFC/ACh liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

30           An observation of the animal's tracheal pressure, before, during and after the pulmonary administration of ACh, demonstrates, among other things, that (a) the tracheal pressure (cm water) increased by about 6 mm Hg after the drug was administered; (b) the increase in  
35       tracheal pressure began almost instantaneously after the drug was administered; and (c) the total time necessary to

increase the tracheal pressure (cm water) by about 5 mm Hg was about 20 seconds.

When testing the dose-dependency effect of the pulmonary administration of epinephrine [Epi], the effect after the administration of the drug (expressed as a percentage of the baseline), as a function of the concentration of the drug, was monitored.

Here, the Epi was dispersed in the PFC liquid medium. The initial amount of Epi dispersed in the PFC liquid was 0.01 mg per each kilogram of the laboratory animal's body weight.

The PFC/Epi liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

Each of the animals tested had at least one of the following parameters recorded before and after the pulmonary administration of the drug: (a) heart rate (bpm), (b) mean arterial pressure (mm Hg), and (c) tracheal pressure (cm water). The averages for each of these recorded parameters were then calculated, depending upon the number of cats tested. These calculated values are plotted on the graph in Figure 36.

The dosage of Epi was then incrementally increased from 0.01 mg/kg up to 1.0 mg/kg. For each incremental increase, the animals tested had at least one of the aforementioned parameters recorded before and after the pulmonary administration of the drug.

Also for each incremental increase, the averages for each recorded parameter were calculated and plotted on the graph in Figure 36.

Referring to Figure 36, the data plotted therein demonstrates that, as a function of increasing the concentration of Epi in the inspired PFC liquid, typical dose-dependent sympathomimetic responses to Epi showed increases in mean arterial pressure (i.e., reflecting vasoconstrict-

tion) and heart rate, and a decrease in peak tracheal pressure (i.e., reflecting bronchodilation).

Another way in which the effect of the pulmonary administration of Epi was tested was by monitoring the change in mean arterial pressure and heart rate resulting from drug delivery.

Here, 0.50 mg/kg of Epi was dispersed in the PFC liquid medium. The PFC/Epi liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

An observation of the animal's tracheal pressure, before, during and after the pulmonary administration of Epi, demonstrates, among other things, a 31% decrease after the drug was administered. Moreover, an observation of the animal's heart rate, before, during and after the pulmonary administration of Epi, demonstrates, among other things, a 33% increase after the drug was administered.

When testing the dose-dependency effect of the pulmonary administration of priscoline [P], the effect after the administration of the drug (expressed as a percentage of the baseline), as a function of the concentration of the drug, was monitored.

Here, the P was dispersed in the PFC liquid medium. The initial amount of P dispersed in the PFC liquid was 4 mg.

The PFC/P liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

Each of the animals tested weighed approximately 3kg. Each of these test animals had at least one of the following parameters recorded before and after the pulmonary administration of the drug: (a) heart rate (bpm), (b) mean arterial pressure (mm Hg), and (c) right ventricular pressure.

The averages for each of the aforementioned recorded parameters were then calculated, depending upon the number of cats tested. These calculated values are plotted on the graph in Figure 37.

5           The dosage of P was then incrementally increased from 4 mg up to 12 mg. For each incremental increase, the animals tested had at least one of the aforementioned parameters recorded before, during and after the pulmonary administration of the drug.

10           Also for each incremental increase, the averages for each recorded parameter were calculated and plotted on the graph in Figure 37.

          Referring to Figure 37, the data plotted therein demonstrates that, as function of increasing the concentration of P in the inspired PFC liquid, typical dose-dependent responses to P showed decreases in mean arterial pressure (i.e., reflecting vasodilation) and right ventricular pressure (i.e., reflecting systemic and pulmonary vasodilation). The heart rate remained fairly constant.

15           Another way in which the effect of the pulmonary administration of P was tested was by monitoring carotid pressure, as a function of time, before, during and after the pulmonary administration of the drug.

20           Here, 12 mg of P was dispersed in the PFC liquid medium. The PFC/P liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

25           A tracing of the animal's carotid pressure, before, during and after the pulmonary administration of P, demonstrates, among other things, that (a) the carotid pressure decreased by about 30 mm Hg after the drug was administered; (b) the decrease in carotid pressure began almost instantaneously after the drug was administered; and (c)  
30           the total time necessary to decrease the carotid pressure  
35           by about 30 mm Hg was about 10 seconds.

When testing the absorption effect of the pulmonary administration of sodium bicarbonate [SBI], the concentration of SBI in the animal's blood, as a function of time, was monitored.

5        Here, 10 mEq of SBI was dispersed in the PFC liquid medium. The PFC/SBI liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

10        An observation of the concentration of SBI present in the animal's blood (monitored as a function of mEq/L) 30 and 120 seconds after the pulmonary administration of SBI, demonstrates, among other things, a respective 4.7% and 20.9% absorption level.

15        When testing the physiological effect of the pulmonary administration of sodium nitroprusside [SNI], the physiological change in the animal's arterial pressure and heart rate, after the administration of the drug, was monitored.

20        Here, 6 mg/kg of SNI was dispersed in the PFC liquid medium. The PFC/SNI liquid medium was then introduced directly into the animal's pulmonary air passages, via the endotracheal tube, during the inspiratory phase of PFC liquid ventilation.

25        An observation of the animal's heart rate, before, during and after the pulmonary administration of SNI, demonstrates, among other things, that it did not significantly change, increase after the drug was administered. Moreover, an observation of the animal's arterial pressure, before, during and after the pulmonary administration of SNI, demonstrates, among other things, a 24% decrease after the drug was administered.

30        It was observed from the above that the pulmonary administration of drugs by liquid ventilation is an effective approach for directly delivering therapeutic agents to the pulmonary and/or systemic systems.

### Conclusions

The foregoing research was highlighted by the first in vivo demonstrations of both acoustic and convective hyperthermia of the lung, here in a suitably large animal model. Controlled and sustained therapeutic temperatures were maintained with relatively few complications. These experiments, complemented by laboratory bench and in vitro acoustic measurements with perfluorocarbon liquids, identified the important clinical requirements for liquid-filled lung ultrasound and convection hyperthermia. Among these are a) lower ultrasound frequencies than traditionally used for soft tissue heating are required, b) traditional bifurcated bronchial catheters are inadequate, mainly due to their thin-walled air cuffs and lack of temperature and pressure instrumentation, and c) the use of degassed perfluorocarbon liquids greatly facilitates the filling of lungs. Of tremendous practical significance are the observations that d) diagnostic ultrasound imaging can be very helpful in assessing the lung filling and the acoustic path available, and e) invasive thermometry will likely not be required for the convection hyperthermia treatments. Additionally, the fundamental fluid and thermal design ranges appropriate to the ultrasound treatment, including the range of inflation pressures, temperatures and tidal volumes, were determined.

Perfluorocarbon liquids have several unique properties. Measurable nonlinear acoustical behavior and scattering in the range of powers suitable to hyperthermia were found in laboratory and animal tests. While dictating the use of lower ultrasound frequencies, these characteristics can be advantageous for spatial smoothing of near field beam patterns and may be able to be exploited for their potential to produce localized enhanced absorption with focused ultrasound beams. In addition, the high gas solubility of perfluorocarbons should serve to suppress

acoustic cavitation in the liquid by retarding rapid gas saturation.

5       The salient design requirements for clinical devices for 1) fluid processing and delivery systems suitable for liquid-filled lung hyperthermia procedures, 2) intracavitary ultrasound applicators for broncho-tracheal tumors, and 3) low-frequency external ultrasound applicators were also determined.

10       In addition to the above, the foregoing research also demonstrates the operability and significant utility of pulmonary administered therapeutic agents through a liquid lavage/ventilation process.

15       While representative and preferred embodiments of the invention have been described and illustrated, it is to be understood that, within the scope of the appended claims, various changes can be made therein. Hence, the invention can be practiced in ways other than those specifically described herein.

## CLAIMS

The embodiments of the invention in which an exclusive property or privilege is claimed are defined as follows:

1. Use of a liquid medium for controlling, diagnosing or treating physiological conditions, diseases or abnormalities of a patient, wherein said liquid medium is passed through at least a portion of the patient's pulmonary air passages by liquid lavage/ventilation, said liquid medium comprising at least one biologically active agent and a liquid carrier comprising one or more perfluorocarbons or physiological saline.

2. Use of a liquid medium recited in claim 1 wherein the pulmonary air passages through which said liquid medium passes comprise the patient's endotracheal tube, pulmonary canals, spaces or volumes in the trachea, left and right bronchi, bronchiolus and/or aveoli of the lungs and the like.

3. Use of a liquid medium as recited in claim 1 or 2 wherein at least one of the physiological conditions, diseases or abnormalities controlled, diagnosed or treated by said liquid medium is pulmonary-related cancer.

4. Use of a liquid medium as recited in claim 3 wherein at least one of the physiological conditions, diseases or abnormalities controlled, diagnosed or treated by said liquid medium is bronchial carcinoma.

5. Use of a liquid medium as recited in claim 3 or 4 wherein the biologically active agent comprises at least one anti-cancer agent.

6. Use of a liquid medium as recited in claim 5 wherein said anti-cancer agent comprises an agent selected from the group consisting of adriamycin, toxins, antibodylinked radionuclides and combinations thereof.

7. Use of a liquid medium as recited in any one of claims 1 to 6 wherein the liquid carrier component of said liquid medium is at least partially breathable.

8. Use of a liquid medium as recited in claim 7 wherein said breathable liquid carrier component comprises perfluorocarbon.

9. Use of a liquid medium as recited in claim 8 wherein said liquid medium is used in the hyperthermic treatment of lung cancer, and wherein the perfluorocarbon is characterized by an average molecular weight in the range from 350 to 560.

10. Use of a liquid medium as recited in claim 9 wherein the perfluorocarbon is further characterized by having:

- (a) viscosity less than 5 CP at 25°C,
- (b) density less than 2.0 g/cm<sup>3</sup> at 25°C,
- (c) boiling point greater than 55°C,
- (d) vapor pressure in the range of from 20 TORR to 200 TORR, and
- (e) Prandtl number less than 10 at 25°C.

11. Use of a liquid medium as recited in claim 8 wherein the perfluorocarbon is selected from the group consisting of FC-84, FC-72, RM-82, FC-75, RM-101, dimethyladamantane trimethylbicyclononane and perfluorodecalin.

12. Use of a liquid medium as recited in any one of claims 1 to 11 wherein, before or during the use of said liquid medium as means for control, diagnosis or treatment, the liquid carrier component of said liquid medium is at a temperature which ranges from between about the patient's normal body temperature to 20% above the patient's normal body temperature.

13. Use of a liquid medium as recited in any one of claims 1 to 11 wherein, before or during the use of said liquid medium as means for control, diagnosis or treatment, the liquid carrier component of said liquid medium is at a temperature which ranges from between the patient's

normal body temperature to 20% below the patient's normal body temperature.

14. Use of a liquid medium as recited in claim 13 wherein at least one of the physiological conditions, diseases or abnormalities controlled, diagnosed or treated by said liquid medium is pulmonary-related cancer, and wherein said liquid medium is used in accordance with the following steps:

(a) temporarily filling at least a portion of a patient's preselected pulmonary air passages, which adjoin pulmonary tissues comprising malignant cells, with said liquid medium,

(b) heating said adjoining pulmonary tissues comprising the malignant cells to a temperature in the range of from 40°C to 50°C by transmitting ultrasound through said liquid medium which fills at least a portion of the patient's pulmonary air passages, and

(c) removing said liquid medium from said patient's preselected pulmonary air passages.

15. Use of a liquid medium as recited in claim 14 wherein the liquid carrier component of said liquid medium is at least partially breathable.

16. Use of a liquid medium as recited in claim 15 wherein the breathable liquid carrier component of said liquid medium comprises perfluorocarbon liquid.

17. Use of a liquid medium as recited in claim 16 wherein the perfluorocarbon liquid carrier component of said liquid medium is characterized by having:

(a) viscosity less than 5 CP at 25°C,

(b) density at less than 2.0 g/cm<sup>3</sup> at 25°C,

(c) boiling point greater than 75°C,

(d) vapor pressure in the range of from about 25 TORR to 100 TORR,

(e) acoustic impedance in the range of from 8.0 to 1.6 Mega Rayls at 37°C,

(f) acoustic attenuation less than 1.2 dB/cm at 1.0 MHz and 45°C, and

(g) an acoustic intensity of 3 W/cm<sup>2</sup>.

18. Use of a liquid medium as recited in claim 15 wherein the breathable liquid carrier component of said liquid medium comprises physiological saline.

19. Use of a liquid medium as recited in claim 14 wherein the ultrasound is in the frequency range of from 250 KHz to 3 MHz.

20. A liquid medium for introduction into pulmonary air passages of a mammalian host, said liquid medium comprising one or more perfluorocarbon liquids and at least one biologically active agent.

21. A liquid medium according to claim 20 wherein the biologically active agent is a therapeutic agent.

22. A liquid medium according to claim 21 wherein the therapeutic agent is an anti-cancer agent.

23. A liquid medium according to any of claims 20-22 wherein the liquid medium is an aqueous perfluorocarbon emulsion.

24. A liquid medium according to any of claims 20-23 wherein the perfluorocarbon is characterized by an average molecular weight in the range from about 350 to about 560.

25. A liquid medium according to claim 24 wherein the perfluorocarbon is characterized by an average molecular weight in the range from 420 to 460.

26. A liquid medium according to any of claims 20-25 wherein the perfluorocarbon is further characterized by having:

- (a) viscosity less than 5 CP at 25°C,
- (b) density less than about 2.0 g/cm<sup>3</sup> at 25°C,
- (c) boiling point greater than 55°C,
- (d) vapor pressure in the range of from 20 TORR to 200 TORR, and
- (e) a Prandtl number less than 10 at 25°C.

27. A liquid medium according to claim 26 wherein the perfluorocarbon has an O<sub>2</sub> solubility of greater than 40 ml/100ml.

28. A liquid medium according to any of claims 20-27 wherein the perfluorocarbon is characterized by having:

- (a) viscosity less than 5 CP at 25°C,
- (b) density less than about 2.0 g/cm<sup>3</sup> at 25°C,
- (c) boiling point greater than 75°C,
- (d) vapor pressure in the range of from 25 TORR to 100 TORR, and
- (e) acoustic impedance in the range of from 0.8 to 1.6 MegaRayls at 37°C, and
- (f) acoustic attenuation less than 1.2 dB/cm at 1.0 MHz at 45°C.

29. A liquid medium according to any of claims 20-23 wherein the perfluorocarbon is selected from the group consisting of FC-84, FC-72, RM-82, FC-75, RM-101, dimethyladamantane, trimethylbicyclononane and perfluorodecalin.

30. A liquid medium according to any of claims 20-29 which is at least partially oxygenated.

31. A liquid medium according to any of claims 20-29 which is substantially degassed.

LIQUID LAVAGE/VENTILATION OF THE  
PULMONARY SYSTEM

Abstract of the Disclosure

5 The invention provides for the pulmonary  
administration of biologically active agents via liquid  
lavage/ventilation.

10 A liquid medium comprising at least one  
biologically active agent and a liquid carrier is passed  
through at least a portion of the patient's pulmonary air  
passages.

15 The liquid medium may be a breathable liquid, such  
as a perfluorocarbon liquid or physiological saline  
solution. Suitable perfluorocarbon liquids having the  
requisite physical and thermal properties are characterized  
by an average molecular weight in the range of from about  
350 to about 560. Representative perfluorocarbon liquids  
are FC-84, FC-72, RM-82, FC-75, RM-101, and perfluoro-  
decalin.
